Rapport de recherche n° 7321. - June 2010 - 16 pages

**Abstract:** We propose an efficient semi-numerical approach to compute the steady-state probability distribution for the number of requests at arbitrary and at arrival time instants in Ph/M/c-like systems in which in the inter-arrival time distribution is represented by an acyclic set of memoryless phases. Our method is based on conditional probabilities and results in a simple computationally stable recurrence. It avoids the explicit manipulation of potentially large matrices and involves no iteration. Due to the use of conditional probabilities, it delays the onset of numerical issues related to floating-point underflow as the number of servers and/or phases increases. For generalized Coxian distributions, the computational complexity of the proposed approach grows linearly with the number of phases in the distribution.

**Keywords:** *G/M/c*-like queue ; steady-state probabilities ; conditionnal probabilities ; recurrence ; acyclic phase distributions

# Une récurrence simple pour la résolution des files de type Ph/M/c/N et Ph/M/c

**Résumé:** Nous proposons une approche semi-numérique afin d'obtenir les probabilités stationnaires du nombre de requêtes dans une file de type Ph/M/c aux instants arbitraires de même qu'aux instants d'arrivée. Notre méthode s'appuie sur l'utilisation des probabilités conditionnelles et débouche sur une récurrence qui s'avère numériquement stable. Cette approche simple ne comporte aucune itération. L'utilisation des probabilités conditionnelles a l'effet bénéfique de retarder l'apparition des problèmes d'arrondi liés au calcul flottant surtout pour un grand nombre de serveur et/ou phases dans la distribution du temps entre arrivées. Lorsque ces derniers sont représentés par une loi de Cox généralisée, la complexité de calcul de notre approche croît de façon linéaire avec le nombre de phases.

**Mots clés:** File de type G/M/c; probabilités stationnaires; probabilités conditionnelles; récurrence; distributions en phase acycliques

#### **1** Introduction

In many computer and networking applications, as well as a number of other areas, the request arrival process exhibits significant deviations from a simple Poisson process. This is the case, for example, for Internet traffic where times between request arrivals are thought to be highly variable and possibly "heavy-tailed" [JIA05, CRO97], as well as for I/O subsystems in large computer installations [HSU03]. To achieve ever increasing performance levels at acceptable energetic expense, a frequent solution entails the use of multiple parallel facilities to process the requests, e.g. in mainframe I/O [IBM99]. If one assumes memoryless service times, the system congestion and the delays experienced by requests become those of a G/M/c-type queue. Since in man-made systems the buffer sizes can only be finite, under heavier workloads, effects due to a limited queueing room cannot be neglected, so that the G/M/c/N-type queue is then a more adequate model. Additionally, in many situations, the service and/or arrival processes may exhibit non-negligible dependence on the current state of the system. For example, state-dependent service rates allow a more accurate representation of service in systems such as multicore processors [VAN08] where, because of interference between processors, the processing capacity does not grow linearly with the number of active processors. State-dependent arrival rates may be useful, for instance, to represent congestion avoidance in IP networks.

Although there are analytical results for the unrestricted state-independent G/M/c queue [BOL05, ALL90, KLE75], their application requires computations which, depending on the specific distribution of inter-arrival times, may quickly become difficult [HAR00, KLE76]. To the best of our knowledge, the G/M/c queue with restricted queueing room has received less attention, and there are few easily usable general analytical results [CHA04, HOK75]. The same seems to apply to G/M/c-type queues with state dependencies [HAR00].

Since any distribution can be approximated arbitrarily closely by a finite number of exponential phases [OCI90, NEU94], a possible approach is to use a phase-type distribution for the times between request arrivals [HOR02, BOB05, OSO06, KHA03, THU06, FEL97], and hence attempt to solve the resulting *Ph/M/c*-type queue.

The matrix-geometric techniques pioneered by Neuts [NEU89, NEU94] are a possible avenue to evaluate such processes. There is a large body of previous work in the area of matrixanalytic approaches. In particular, Latouche and Ramaswami [LAT93] propose the logarithmic reduction algorithm as a numerically stable approach to the computation of steady-state probabilities in level-independent systems, i.e., systems without state dependency. This algorithm is based on stochastic complementation [RIS02]. The work of Gaver et al. [GAV84] is devoted to finite queues in randomly changing environments, and includes a numerical method that involves a recursive determination of certain matrices. The logarithmic reduction algorithm of Latouche and Ramaswami has been extended by Bright and Taylor [BRI95] to level-dependent infinite queues. Bright and Taylor point out possible numerical problems in their approach due to the recursive calculation of matrices involved in the solution. Gaver et al [GAV84] mention similar problems. Latouche shows in [LAT94] that the Newton's method applied to non-linear equations in Markov chains is quadratically convergent although not very attractive because of its computational complexity. Akar and Sohraby [AKA97] propose an invariant subspace approach whose convergence rates are at least quadratic, and whose accuracy may be better due to the avoidance of truncation. The generalization of matrix-geometric stationary distribution to level-dependent quasi-birth-and-death processes is considered by Ramaswami and Taylor [RAM96]. Bean et al. [BEA00] study the quasistationary distributions for level-dependent processes and propose a method derived from the Latouche-Ramaswami algorithm for their computation. The work of Ye [YE02] examines the theoretical properties of the Latouche-Ramaswami logarithmic reduction algorithm, including numerical stability issues, and offers a more stable algorithm for inverting a diagonally dominant matrix. An improved matrixgeometric algorithm is proposed by Naoumov et al. [NAO96]. The spectral expansion method can also be applied to obtain a solution for these types of systems [MIT95, MIT91, ELW91].

We refer the reader to the books by Latouche and Ramaswami [LAT99], Bini et al. [BIN05], and, at a more introductory level, by Bolch et al. [BOL05] for an overview of properties of matrix-analytic approaches and numerical methods for quasi-birth-and-death problems and G/M/1-type Markov chains. Bini et al. [BIN06a, BIN06b] discuss practical considerations and software implementation for several of the methods mentioned above. Mitrani and Chakka [MIT95] compare the performance of the spectral expansion and matrix-geometric methods for an M/M/c-type queue. Haverkort and Ost [HAV97] also compare the spectral expansion method with the Latouche-Ramaswami algorithm for a model of a fault-tolerant system. Tran and Do [TRA00] present a comparison of the practical performance of matrix-geometric methods and of the spectral expansion for a specific quasi birth-and-death process.

We propose a considerably simpler semi-numerical approach to compute the steady-state probability distribution for the number of requests in the system both at arbitrary times and at instants of request arrival for Ph/M/c-type queues with and without state-dependencies. Our method, inspired by a recent semi-numerical solution for  $M/C_n/l$ -type queues [BRA08], exploits the known form of the steady-state distribution, involves no iteration, and results in a simple numerically stable recurrence. It avoids the explicit manipulation of potentially large matrices, and, because of the use of conditional probabilities, reduces the possibility of floating-point numerical problems, especially as the number of servers and/or phases increases.

This paper is organized as follows. In the next section, we describe in more detail the Ph/M/c-type and Ph/M/c/N-type models considered and the proposed recurrent solution. Section 3 presents a formal proof of computational stability of our recurrent solution. In Section 4 we discuss the computational complexity of our approach, and present an example of numerical results obtained using it. Section 5 concludes this note.

#### 2 Model and its recurrent solution

#### 2.1 State description

The queue considered is shown in Figure 1. There are c homogenous servers. The service times are assumed to be memoryless with individual service rate  $\mu(n)$  where n is the current number of requests in the system. In the case of a restricted queueing room, N is the maximum value for this number.

Similarly to several authors [NEU94, LAT99], we represent the times between arrivals as a phase-type distribution, which we assume to be acyclic. We denote by *a* the number of memoryless phases, by  $\tau_j(n)$  the probability that the arrival process starts in phase j, j = 1,...,a, by  $\lambda_j(n)$  the rate of phase *j*, by  $r_{ji}(n)$  (l > j) the phase transition probabilities, and by  $\hat{r}_j(n)$  the probability that the arrival process terminates after phase *j*. We consider this queue in steady state for which the joint probability of the current stage of the arrival process and the current number of requests in the system, p(j,n), is a common description. Table 1 summarizes the principal notation used in this note.

Table 1. Principal notation used.

с	Number of servers
п	Total current number of requests in the system; $n = 0,,N$ for a finite queueing
	room
$\tau_j(n)$	Probability that arrival process starts in phase $j$ , $j = 1,,a$ when there are $n$
	requests in the system
$\lambda_j(n)$	Completion rate for phase <i>j</i> of arrival process
$r_{jl}(n)$	Probability that arrival process continues in phase <i>l</i> upon completion of phase
	j, j, l = 1,,a, l > j
$\hat{r}_{j}(n)$	Probability that arrival process ends (new request generated) upon completion
	of phase $j, j = 1,,a$

u(n)	Rate of request completions given by $\min(c,n)\mu(n)$ where $\mu(n)$ is the service
	rate of a single server
u <sup>*</sup>	Limiting value of $u(n)$ with unrestricted queueing room
$p(j \mid n)$	Conditional probability that the arrival stage is <i>j</i> given that the number in the
	system is <i>n</i>
$\alpha(n)$	Conditional rate of arrivals given that the number in the system is $n$ (cf. (2))
ã	Limiting value of $\alpha(n)$ with unrestricted queueing room
<i>p</i> ( <i>n</i> )	Steady-state probability that the number of customers in the system is $n$
$P_A(n)$	Probability that an arriving customer finds $n$ customers already present in the
	system
n <sup>*</sup>	Number of requests for which the state dependence ends for arrivals and service
	$(\tilde{n} = n^* + 1)$
$\tilde{ ho}$	Limiting geometric factor for an unrestricted queue

#### 2.2 Restricted queueing room (*Ph/M/c/N*-type queue)

We first consider the case where the queueing room is finite so that no more than N(N > c) requests can be in the system (queued and in service). With a finite queueing room, there are several possible assumptions regarding the arrival process when the buffer is full. One simple possibility is that requests arriving to find the buffer full are simply lost (lost arrivals) and the arrival process continues unperturbed. Another possibility, of interest in networking applications, is that the arrival process stops altogether when the buffer becomes full, and remains blocked until a request leaves the system (blocked arrivals). Our approach can accommodate both assumptions.

It is a straightforward matter to obtain the balance equations for the steady-state probability p(j,n) that the current stage of the arrival process is j and that the current number of requests is n. It is also not difficult to show that the marginal probability that there are n requests in the system, p(n), can be expressed as

$$p(n) = \frac{1}{G} \prod_{m=1}^{n} \alpha(m-1)/u(m), \quad n = 0, 1, \dots$$
(1)

where

$$\alpha(n) = \sum_{j=1}^{a} \lambda_j(n) \hat{r}_j(n) p(j \mid n), \qquad (2)$$

and  $u(n) = \min(c,n)\mu(n)$ , and G is a normalizing constant chosen so that  $\sum p(n) = 1$ .

From the definition of conditional probability, we have p(j,n) = p(j|n)p(n). Using this relationship together with (1) in the balance equations we obtain for n = 0,1...,N-1 in the case of lost arrivals

$$p(j|n)[\lambda_j(n) + u(n)] = p(j|n+1)\alpha(n) + \sum_{l=1}^{j-1} \lambda_l(n) r_{lj}(n) p(l|n) + \tau_j(n)u(n), \ j = 1,...,a.$$
(3)

With lost arrivals, for n = N we have

$$p(j|N)[\lambda_j(N) + u(N)] = \sum_{l=1}^{j-1} \lambda_l(N) r_{lj}(N) p(l|N) + \tau_j(N) u(N) + \tau_j(N) \alpha(N), \ j = 1, ..., a$$
(4)

The equations for the case of blocked arrivals are given in the Appendix. Clearly, we have

$$\sum_{j=1}^{n} p(j|n) = 1, \ \forall n = 0,1...$$
(5)

Based on the form of equations (4) and (3), we let

$$p(j|n) = \varphi_j(n)\alpha(n) + \xi_j(n)u(n).$$
(6)

We start from n = N. Using (6) in equation (4) we readily obtain the coefficients  $\varphi_j(N)$  and  $\xi_j(N)$  in the order j = 1,...,a (cf. eqs (18) and (19) in the Appendix). From (6) and the normalizing condition (5) we determine  $\alpha(N)$ . We are thus able to compute p(j|N) using  $\alpha(N)$  and

the previously computed coefficients  $\varphi_j(N)$  and  $\xi_j(N)$  in (6). We then consider consecutive decreasing values of n = N - 1,...,0. For each *n*, the values of p(j|n+1) are known, and we easily determine the coefficients  $\varphi_j(n)$  and  $\xi_j(n)$  using (6) in (3) (cf. Appendix (18) and (19)). We obtain  $\alpha(n)$  using (6) in the normalizing condition (5), and hence p(j|n) from (6). Details of the recurrent computation are shown in the Appendix.

Having obtained the values of  $\alpha(n)$  for n = 0,1..., we are ready to compute the steady-state probabilities for the number of requests in the system p(n) from equation (1).

The probability that an arriving customer finds *n* customers already present in the system,  $P_A(n)$ , can be expressed as

$$P_{A}(n) = \frac{\alpha(n)p(n)}{\sum_{i} \alpha(i)p(i)}, n = 0, 1, ...$$
(7)

From (7), it follows that the loss probability in the case of lost arrivals is given by  $P_A(N)$ . In the case of blocked arrivals, we have  $\alpha(N) = 0$  so that, as expected,  $P_A(N) = 0$ . The fraction of time during which the arrival process is blocked is then given by p(N). Note that  $\alpha(n)$  is the conditional state-dependent rate of arrivals, and exhibits in general a strong non-trivial dependence on n, except in the case of a Poisson arrival process, in which case  $\alpha(n)$  is a constant.

#### 2.3 Unrestricted queueing room (*Ph/M/c*-type queue)

We now consider the case of an unrestricted buffer size. We assume that the statedependencies in the arrival process and in the service rate vanish starting with some value of the number of requests in the system, say,  $n = n^*$ , so that we have  $\tau_j(n) = \tau_j^*$ ,  $\lambda_j(n) = \lambda_j^*$ ,  $r_{jl}(n) = r_{jl}^*$ ,  $\hat{r}_j(n) = \hat{r}_j^*$  and  $\mu(n) = \mu^*$  (and hence  $u(n) = u^* = c\mu^*$ ) for  $n \ge n^*$ . Following a reasoning similar to the one used for a standard *G/M/c* queue [KLEI 75 page 246], it can be shown that the distribution of the number of requests found at arrival instants is geometric for  $n > n^*$ . It is easy to show that the steady-state probabilities p(n) are also geometrically distributed for  $n > n^*$ . The geometric factor being  $\alpha(n)/u^*$ , it follows that, for the case  $n > n^*$ , the  $\alpha(n)$  reach their limiting value  $\tilde{\alpha}$ . Thus, from (2), the conditional probabilities p(j|n) must also reach their limiting values  $\tilde{p}(j)$ . The limiting value  $\tilde{\alpha}$  is given by

$$\tilde{\alpha} = \sum_{j=1}^{\infty} \tilde{p}(j) \lambda_j^* r_j^* \,. \tag{8}$$

Hence, for  $\tilde{n} = n^* + 1$ , the values of p(j|n) become equal to  $\tilde{p}(j)$  and  $\alpha(n) = \tilde{\alpha}$ . Denoting the geometric factor by  $\tilde{\rho} = \tilde{\alpha}/u^*$  we have

$$p(n) = \frac{1}{G} \begin{cases} \prod_{k=1}^{n} \alpha(k-1)/u(k), & n \le \tilde{n} \\ \left[ \prod_{k=1}^{\tilde{n}} \alpha(k-1)/u(k) \right] \tilde{\rho}^{n-\tilde{n}}, & n > \tilde{n} \end{cases}$$
(9)

The normalizing constant G can be written as

$$G = 1 + \sum_{n=1}^{\bar{n}-1} \prod_{k=1}^{n} \alpha(k-1)/u(k) + \left[\prod_{k=1}^{\bar{n}} \alpha(k-1)/u(k)\right] \frac{1}{1-\tilde{\rho}}.$$
(10)

Clearly, we must have  $\tilde{\rho} < 1$ , i.e.,  $\tilde{\alpha} < u^*$  for the steady-solution to exist. An in-depth discussion of stability and related issues in a muti-server queue can be found in the work of Kiefer and Wolfowitz [KIE55] and Scheller-Wolf and Sigman [SCH97].

The limiting values  $\tilde{p}(j)$  and  $\tilde{\alpha}$  can be determined from the limit of equation (3) for  $n \to \infty$ 

$$\tilde{p}(j)(\lambda_{j}^{*}+u^{*}) = \tilde{p}(j)\tilde{\alpha} + \sum_{l=1}^{j} \lambda_{l}^{*} r_{lj}^{*} \tilde{p}(l) + \tau_{j}^{*} u^{*}, \quad j = 1, ..., a.$$
(11)

Obviously, we must have  $\sum_{j=1}^{n} \tilde{p}(j) = 1$ . Based on this fact, a simple bisection can be used to solve equation (11) (see Appendix).

Thus, starting from the value  $\tilde{n} = n^* + 1$  and using the limiting values  $\tilde{p}(j)$  as  $p(j|\tilde{n}+1)$ , we compute the values of p(j|n) (j=1,...,a) and  $\alpha(n)$  for consecutive decreasing values of  $n = \tilde{n}, \tilde{n} - 1,..., 0$  from recurrence (3) as described in the preceding section.

In the case of a standard Ph/M/c queue, i.e., when there are no state dependencies in the arrival process or the service rate, the steady-state probabilities p(n) are known to have a geometric form starting from n = c [KLE75, ALL90 page 698]. Therefore, it is clear that our asymptotic factor  $\tilde{\rho}$  coincides with the solution of the well-known equation involving the Laplace-Stieltjes transform of the inter-arrival time distribution (see e.g. [BOL05 equation (6.85) page 265, ALL90 page 698). Thus, the simple bisection (cf. Appendix) for the limiting probabilities  $\tilde{p}(j)$  (equation (11)) provides an alternate way of computing this solution.

#### **3** Stability of recurrent solution

In this section we show that our recurrent solution is computationally stable. We follow closely the line of reasoning presented for M/G/l-like queues [BRA08], adapting it to the distribution type and queue considered in this note. We write the recurrence as

$$p(j \mid n)[\lambda_{j}(n) + u(n)] = p(j \mid n+1)\alpha(n) + \sum_{l=1}^{j-1} \lambda_{l}(n)r_{lj}(n)p(l \mid n) + \tau_{j}(n)u(n), \ j = 1,...,a$$

where we use the following notation  $p(j|N+1) = \tau_j$ ,  $\forall j$ , in the case of a finite buffer with lost arrivals, and p(j|N) = 0,  $\forall j$ , in the case of a finite buffer with blocking.

As described in Section 2, the solution can be expressed as  

$$p(j|n) = \varphi_{i}(n)\alpha(n) + \xi_{i}(n)u(n)$$
(12)

with the coefficients  $\varphi_i(n)$  and  $\xi_i(n)$  given by

$$\varphi_{j}(n)[\lambda_{j}(n) + u(n)] = p(j \mid n+1) + \sum_{l=1}^{j-1} \lambda_{l}(n)r_{lj}(n)\varphi_{l}(n), \quad j = 1,...,a$$
(13)

$$\xi_{j}(n)[\lambda_{j}(n) + u(n)] = \sum_{l=1}^{n-1} \lambda_{l}(n)r_{lj}(n)\xi_{l}(n) + \tau_{j}(n), \quad j = 1, \dots, a.$$
(14)

From (6) and (5) we get for  $\alpha(n)$ 

$$\alpha(n) = [1 - u(n)\sum_{j=1}^{k} \xi_{j}(n)] / \sum_{j=1}^{k} \varphi_{j}(n).$$

We assume that the phase-type distribution of the time between arrivals has indeed a stages, so that

$$\lambda_j(n) > 0$$
 and  $\tau_j(n) + \sum_{l=1}^{j-1} r_{lj}(n) > 0$  for  $j = 1, ..., a$  (in particular,  $\tau_1(n) > 0$ )

We first show that our recurrence for p(j|n) produces positive values. Lemma 1:

If p(j|n+1) > 0 for i > 1, then we have

- 1.  $\varphi_i(n) > 0$  and  $\xi_i(n) > 0$  for  $j \ge 1$ ,
- 2.  $\alpha(n) > 0$ , and

3. p(j|n) > 0 for  $j \ge 1$ .

Proof of Lemma 1:

- 1. follows directly from (13) and (14).
- 2. Summing (14) over all values of j and using the fact that  $\sum_{j=1}^{n} \tau_j(n) = 1$ , we get

$$\sum_{j=1}^{a} \xi_{j}(n) [\lambda_{j}(n) + u(n)] = \sum_{j=1}^{a} \sum_{l=1}^{j-1} \lambda_{l}(n) r_{lj}(n) \xi_{l}(n) + 1$$

Rearranging the terms and using the fact that  $\sum_{j=i+1}^{a} r_{ji}(n) = 1 - \hat{r}_{j}(n)$ , we have

$$1-u(n)\sum_{j=1}^{a}\xi_{j}(n)=\sum_{j=1}^{a}\xi_{j}(n)\lambda_{j}(n)\hat{r}_{j}(n)>0, \text{ and hence } \alpha(n)>0.$$

3. Follows directly from the results of 1) and 2).

Lemma 1 establishes that p(j|n) > 0 for  $j \ge 1$  and  $n \ge 0$ .

Consider now a set of perturbed conditional probabilities, where the perturbation corresponding to floating point roundoff errors,

 $\tilde{p}(j | n+1) = p(j | n+1) + \Delta p_j^{(n+1)}.$ 

Because the conditional probabilities are normalized at each step of the recurrence, the perturbations  $\Delta p_j^{(n+1)}$  must satisfy

 $\sum_{j=1}^{a} \Delta p_{j}^{(n+1)} = 0.$  We assume that the perturbations are small so that we have  $\tilde{p}(j|n+1) > 0$ . From (14) it is clear that the perturbation does not affect  $\xi_{j}(n)$ . Let  $\tilde{\varphi}_{j}(n) = \varphi_{j}(n) + \Delta \varphi_{j}^{(n)}$  be the solution of (13) when p(j|n+1) is replaced by  $\tilde{p}(j|n+1)$ .  $\Delta p_{j}^{(n+1)}$  and  $\Delta \varphi_{j}^{(n)}$  are related by

$$\Delta \varphi_{j}^{(n)}[\lambda_{j}(n) + u(n)] = \sum_{l=1}^{j-1} \lambda_{l}(n) r_{lj}(n) \Delta \varphi_{l}^{(n)} + \Delta p_{j}^{(n+1)}.$$
(15)

In Lemma 2 we bound relative perturbations in  $\varphi_j(n)$  in terms of relative perturbations in p(j|n+1).

Lemma 2:

$$\Delta p_j^{(n+1)} \text{ and } \Delta \varphi_j^{(n)} \text{ satisfy}$$
$$\max_j \frac{\Delta \varphi_j^{(n)}}{\varphi_j(n)} \le \max_j \frac{\Delta p_j^{(n+1)}}{p(j|n+1)}$$

$$\min_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} \ge \min_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j \mid n+1)}$$

Proof of Lemma 2: see Appendix.

Let  $\tilde{p}(j|n) = p(j|n) + \Delta p_j^{(n)}$  be the conditional probabilities at *n* corresponding to  $\tilde{p}(j|n+1)$ .  $\tilde{p}(j|n)$  is expressed in (12) as

 $\tilde{p}(j \mid n) = \tilde{\varphi}_{i}(n)\tilde{\alpha}(n) + \xi_{i}(n)u(n)$ 

where

$$\tilde{\alpha}(n) = \left[1 - u(n)\sum_{j=1}^{a} \xi_{j}(n)\right] / \sum_{j=1}^{a} \tilde{\varphi}_{j}(n).$$

The following lemma relates  $\Delta p_i^{(n)}$  to  $\Delta \varphi_i^{(n)}$ .

Lemma 3:

 $\Delta p_{j}^{(n)} \text{ satisfies}$   $\frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)} = \frac{1}{1 + \Delta\beta^{(n)}} \left[ \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} - \Delta\beta^{(n)} \right]$ where  $\Delta \beta^{(n)} = \sum_{j=1}^{a} \Delta \varphi_{j}^{(n)} / \sum_{j=1}^{a} \varphi_{j}(n).$ 

Proof of Lemma 3: see Appendix.

The preceding lemmas give us the elements to prove the stability of our recurrent algorithm. We consider the following function to assess the magnitude of the relative error in p(j|n)

$$g(n) = \frac{\max_{j} \frac{\Delta p_{j}^{(n)}}{p(j|n)} - \min_{j} \frac{\Delta p_{j}^{(n)}}{p(j|n)}}{1 + \min_{j} \frac{\Delta p_{j}^{(n)}}{p(j|n)}}.$$

 $\frac{\text{$ **Theorem 1:** $}}{g(n) \text{ satisfies}}$ 

1.  $g(n) \le g(n+1)$ 2.  $\max_{j} \left| \frac{\Delta p_{j}^{(n)}}{p(j+n)} \right| \le g(n)$ 

Proof of Theorem 1:

1. Because  $\sum_{i=1}^{a} \Delta p_{j}^{(n)} = 0$ , we must have  $\max_{i} \frac{\Delta p_{j}^{(n)}}{\pi(1+1)} \ge 0 \text{ and } \min_{j=1} \frac{\Delta p_{j}^{(n)}}{\pi(1+1)} \le 0.$ 

$$p(j|n) = 0 \quad \text{and} \quad \lim_{j \to 0} p(j|n) = 0 \quad (16)$$

Using (12) and the results of Lemma 1, we have  $\mathbf{An}^{(n)}$ **A** ... (n)

$$\max_{j} \frac{\Delta p_{j}^{(n)}}{p(j|n)} \le \max_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)} \text{ and } \min_{j} \frac{\Delta p_{j}^{(n)}}{p(j|n)} \ge \min_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)}$$
  
Substituting into function  $a(n)$  we obtain

Substituting into function g(n) we obtain  $\mathbf{A} = (n)$  $\mathbf{A} = (n)$ 

$$g(n) \leq \frac{\max_{j} \frac{\Delta p_{j}}{\alpha(n)\varphi_{j}(n)} - \min_{j} \frac{\Delta p_{j}}{\alpha(n)\varphi_{j}(n)}}{1 + \min_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)}}$$

From the results of Lemma 2 and Lemma 3 we have

$$\left[\max_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)} - \min_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)}\right] = \frac{1}{1 + \Delta \beta^{(n)}} \left[\max_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} - \min_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)}\right]$$
  
$$\leq \frac{1}{1 + \Delta \beta^{(n)}} \left[\max_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j|n+1)} - \min_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j|n+1)}\right]$$
  
and

$$1 + \min_{j} \frac{\Delta p_{j}^{(n)}}{\alpha(n)\varphi_{j}(n)} = \frac{1}{1 + \Delta\beta^{(n)}} \left[ 1 + \min_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} \right] \ge \frac{1}{1 + \Delta\beta^{(n)}} \left[ 1 + \min_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j|n+1)} \right] > 0.$$

Combining these results yields  $g(n) \le g(n+1)$ .

2. Using (16), we conclude that

$$g(n) \ge \max_{j} \frac{\Delta p_{j}^{(n)}}{p(j \mid n)} - \min_{j} \frac{\Delta p_{j}^{(n)}}{p(j \mid n)} \ge \max_{j} \left| \frac{\Delta p_{j}^{(n)}}{p(j \mid n)} \right|$$

Thus, Theorem 1 shows that our recurrent algorithm is numerically stable. In the next section we discuss the computational complexity of our method and present a numerical result that illustrates its application.

#### **4** Performance of the method

We start by a brief discussion of the computational complexity of our recurrent solution. In the case of a finite queueing room of size N, i.e., the Ph/M/c/N-type queue, the total number of floating point operations can be evaluated in advance. It varies with the precise nature of the phase-distribution considered, and can be expressed as  $o(Na^k)$  where  $k \le 3$ . For the generalized Coxian distribution where (with the exception of the last stage)  $r_{il} = 0$  for any  $l \neq j+1$ , we have k = 1. Thus, for these types of distribution, which include the Erlang and the hyper-exponential distribution, the complexity is o(Na). The maximum value of k = 3 is reached for a general acyclic distribution.

In the case of an unrestricted queueing room, i.e., the Ph/M/c-type queue, the first step is to solve for the limiting probabilities  $\tilde{p}(j)$ . This step may involve a slightly variable, but generally modest (say, a few tens), number of bisection points (cf. Appendix). The complexity of each bisection point is  $o(a^k)$ , where the value of k depends on the type of distribution of the time between arrivals as discussed for the *Ph/M/c/N*-type queue. The second step involves our recurrence, and its complexity is  $o(\tilde{n}a^k)$ .

In both cases, the memory space requirements of our approach are limited: an array of aelements to hold the probabilities p(j|n) for a single value of n at a time, two arrays of a ele-

RR n° 7321

ments for the coefficients  $\varphi_j$  and  $\xi_j$ , and a single array of (N+1) (or  $(\tilde{n}+1)$ ) elements to store the values of  $\alpha(n)$ .

Note that our recurrence requires no special arrangements for state-dependent systems. Note also that by using the conditional probabilities p(j|n), as opposed to the regular state probabilities p(j,n), we partition the state space into a set of subspaces individually normalized for each value of the number of requests n. This has the effect of scaling up the numerical values manipulated, thus delaying the onset of loss of precision due to floating-point underflow problems. Depending on the number of stages and the specific instance of the phase-type distribution, such problems might otherwise occur even for moderate numbers of servers.

To illustrate the application of our method, we consider a system with 32 servers, a Paretolike distribution of the time between arrivals and a finite buffer of 64 requests. Such bursty distributions have been reported in I/O subsystems (e.g., [HSU03]), as well as computer networks (e.g., [JIA05, CRO97].) The number of servers chosen might correspond, for instance, to the number of "exposures" in the case of Parallel Access Volumes [IBM99] in a mainframe I/O subsystem. The phase-type representation of the Pareto-like distribution was obtained using the PhFit software [HOR02]. It contains 16 phases, 6 of which are used for the heavy-tail part of the distribution. We represent in Figure 1 the results obtained using our method at close to 80% server utilization. These results include the steady-state average-time probabilities p(n) and the probabilities of the state upon arrival  $P_A(n)$ .

In Section 3 we have presented a theoretical proof that the proposed recurrence is computationally stable, and, in the many numerical examples we have considered, we found the method to be numerically stable in practice.

Figure 1. Distributions of number of requests at arbitrary times and upon arrival.

#### **5** Conclusions

In this note we propose a simple recurrent solution of Ph/M/c/N-type and Ph/M/c-type queues. The queues considered may have state-dependent arrival and service processes. For systems with finite buffers, the proposed method can handle queues with lost arrivals, as well as with blocking.

We derive our recurrent solution by considering the conditional probabilities of the arrival process given the number of requests in the system. The resulting recurrence yields the state-dependent arrival rates, and, hence, the steady-state probabilities for the number of requests both at arbitrary times and at instants of arrival. The solution is exact, and involves no iteration. In the case of an unrestricted queueing room, the solution involves the computation of the limit-

nria-00492748, version 1 - 16 Jun 2010

ing geometric factor ( $\tilde{\rho} = \tilde{\alpha}/u^*$ ) and the limiting conditional probabilities before the actual recurrence. A simple bisection can be used to accomplish this task.

The proposed solution is reasonably scalable as the number of servers and phases increases. For a generalized Coxian distribution of the inter-arrival times, its computational complexity is o(Ma), and it is  $o(Ma^3)$  for an arbitrary acyclic phase-type distribution, where *a* is the number of phases and *M* is the maximum population level for the recurrence, i.e., *N* for the *Ph/M/c/N*-type and  $\tilde{n}$  for the *Ph/M/c*-type queue. It is interesting to note that, for phase-type distributions, many distribution fitting methods use the generalized Coxian distribution (or some simplified form thereof) [HOR02, BOB05, OSO06, KHA03, THU06, FEL97], for which the complexity of the proposed recurrent solution grows linearly with the number of stages.

The use of conditional probabilities, as opposed to the joint probabilities of the current arrival phase and the number of customers in the system, has the distinct advantage of dividing the state space into subspaces individually normalized for each population level. This scales up the values manipulated by the computation thus delaying the onset of numerical issues related to floating-point underflow.

We present a theoretical proof that our recurrent solution is computationally stable, and our numerical trials indicate that the method is numerically stable in practice even with large numbers of phases. Our recurrent solution requires minimal memory space. It is also very simple to implement in a standard computer language.

#### 7 Appendix

#### 7.1 Limiting probabilities with unrestricted queueing room

To devise a simple solution for equation (11), let us treat the limiting rate of arrivals  $\tilde{\alpha}$  as a parameter and write the equation as

$$\tilde{p}(j) = \frac{1}{(\lambda_j^* + u^* - \tilde{\alpha})} \left[ \sum_{l=1}^{j-1} \lambda_l^* r_{ij}^* \tilde{p}(l) + \tau_j^* u^* \right], \quad j = 1, ..., a.$$
(17)

For  $\tilde{\alpha} < u^* + \min \lambda_i^*$ ,  $\tilde{p}(j)$  is a strictly increasing function of  $\tilde{\alpha}$ . For  $\tilde{\alpha} = 0$ , summing (17) over

all values of j, and dividing by  $u^*$ , we get  $\sum_{j=1}^{a} \tilde{p}(j) = 1 - \frac{1}{u^*} \sum_{j=1}^{a} \lambda_j \hat{r}_j^* < 1$ . On the other hand, as

$$\tilde{\alpha} \to u^* + \min_j \lambda_j, \sum_{j=1}^{\infty} \tilde{p}(j) \to \infty > 1.$$
 Since  $\sum_{j=1}^{\infty} \tilde{p}(j)$  is a continuous strictly increasing function of  $\tilde{\alpha}$ ,

there must be a unique value of  $\tilde{\alpha}$  such that  $\sum_{j=1}^{d} \tilde{p}(j) = 1$ . Given the geometric nature of the limiting distribution of the number of requests in the system, we must have  $\tilde{\alpha} < u^*$  if the queue is to be stable.

Thus, the limiting solution can be obtained through a simple bisection looking for a value  $\tilde{\alpha} \in (0, u^*)$  for which  $\sum_{i=1}^{a} \tilde{p}(i) = 1$ .

#### 7.3 Details of the recurrent computation

We look for a solution to equation (3) of the form  $p(j|n) = \varphi_j(n)\alpha(n) + \xi_j(n)u(n)$ . For our purpose here, we let  $p(j|N+1) = \tau_j, \forall j$ . Equation (3) then implies

$$\varphi_{j}(n) = \frac{1}{[\lambda_{j}(n) + u(n)]} \{ p(j \mid n+1) + \sum_{l=1}^{j-1} \lambda_{l}(n) r_{lj}(n) \varphi_{l}(n) \}, \ j = 1, ..., a$$
(18)

and

14

$$\xi_{j}(n) = \frac{1}{[\lambda_{j}(n) + u(n)]} \{\sum_{l=1}^{j-1} \lambda_{l}(n) r_{lj}(n) \xi_{l}(n) + \tau_{j}(n)\}, \ j = 1, ..., a$$
(19)

The unknown  $\alpha(n)$  is determined from the normalizing condition (5)

$$\alpha(n) = [1 - u(n)\sum_{j=1}^{n} \xi_j(n)] / \sum_{j=1}^{n} \varphi_j(n).$$
<sup>(20)</sup>

The computation for n = N - 1 in the case of communication blocking proceeds in an analogous way.

Our recurrent computation can be summarized as follows:

For *n* from *N* to 0  
Do  
• Compute coefficients 
$$\varphi_j(n)$$
 and  $\xi_j(n)$  for *j* from 1 to *a*  
• Compute  $\alpha(n)$  using (20)

• Compute p(j|n) for j from 1 to a using (6) EndFor Compute p(n) and  $P_4(n)$  using (1) and (7)

7.4 Proof of Lemmas 2 and 3

Proof of Lemma 2: Suppose  $\max_{i} \frac{\Delta \varphi_{i}^{(m)}}{\omega_{i}(n)}$  is attained at j = m. Then, for j = m, we can write (15) as  $\left[\frac{\Delta \varphi_m^{(n)}}{\varphi_m(n)}\right]\varphi_m(n)[\lambda_m(n) + u(n)] - \sum_{l=1}^{m-1} \left[\frac{\Delta \varphi_l^{(n)}}{\varphi_l(n)}\right]\varphi_l(n)\lambda_l(n)r_{lm}(n) = \left[\frac{\Delta p_m^{(n+1)}}{p(m \mid n+1)}\right]p(m \mid n+1)$ which leads to  $\left[\frac{\Delta \varphi_m^{(n)}}{\varphi_m(n)}\right] \{\varphi_m(n)[\lambda_m(n)+u(n)] - \sum_{l=1}^{m-1} \varphi_l(n)\lambda_l(n)r_{lm}(n)\} \leq \left[\frac{\Delta p_m^{(n+1)}}{p(m \mid n+1)}\right] p(m \mid n+1).$ On the other hand, at j = m, (13) becomes  $\varphi_m(n)[\lambda_m(n)+u(n)] - \sum_{l=1}^{m-1} \varphi_l(n)\lambda_l(n)r_{lm}(n) = p(m \mid n+1).$ Combining these two results, yields  $\max_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} = \frac{\Delta \varphi_{m}^{(n)}}{\varphi_{m}(n)} \leq \frac{\Delta p_{m}^{(n+1)}}{p(m \mid n+1)} \leq \max_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j \mid n+1)}.$ In an analogous manner, we obtain  $\min_{j} \frac{\Delta \varphi_{j}^{(n)}}{\varphi_{j}(n)} \ge \min_{j} \frac{\Delta p_{j}^{(n+1)}}{p(j \mid n+1)}$ Proof of Lemma 3:  $\Delta \alpha(n) = \tilde{\alpha}(n) - \alpha(n)$  $=\frac{1-u(n)\sum_{j=1}^{a}\xi_{j}(n)}{\sum_{i=1}^{a}\left[\varphi_{j}(n)+\Delta\varphi_{j}^{(n)}\right]}-\frac{1-u(n)\sum_{j=1}^{a}\xi_{j}(n)}{\sum_{i=1}^{a}\varphi_{j}(n)}$  $=\frac{-\left(1-u(n)\sum_{j=1}^{a}\xi_{j}(n)\right)\left(\sum_{j=1}^{a}\Delta\varphi_{j}^{(n)}\right)}{\left(\sum_{j=1}^{a}\varphi_{j}(n)\right)\left(\sum_{j=1}^{a}\varphi_{j}(n)+\sum_{i=1}^{a}\Delta\varphi_{j}^{(n)}\right)}=-\alpha(n)\frac{\Delta\beta^{(n)}}{1+\Delta\beta^{(n)}}$  $\Delta p_{i}^{(n)} = \tilde{p}(j \mid n) - p(j \mid n)$  $= \left[\varphi_{j}(n) + \Delta \varphi_{j}^{(n)}\right] \left[\alpha(n) + \Delta \alpha(n)\right] - \alpha(n)\varphi_{j}(n)$  $= \alpha(n)\Delta\varphi_{i}^{(n)} + \Delta\alpha(n) \left[\varphi_{i}(n) + \Delta\varphi_{i}^{(n)}\right]$  $=\alpha(n)\left[\Delta\varphi_{j}^{(n)}-\frac{\Delta\beta^{(n)}}{1+\Lambda\beta^{(n)}}\left[\varphi_{j}(n)+\Delta\varphi_{j}^{(n)}\right]\right]=\frac{\alpha(n)}{1+\Lambda\beta^{(n)}}\left[\Delta\varphi_{j}^{(n)}-\Delta\beta^{(n)}\varphi_{j}(n)\right]$ 

#### 7.5 *Ph/M/c/N* queue with blocking

We consider here communications type of blocking where the arrival process is stopped altogether when the number of requests in the system becomes N. The arrival process then restarts after the departure of a request. For this type of blocking, the equations for the top two values of n change. For n = N, there are no arrivals, the probabilities p(j|N) are meaningless and  $\alpha(N) = 0$  (of course, p(N) is in general non zero.) For n = N - 1, we get

RR n° 7321

$$p(j|N-1)[\lambda_{j}(N-1)+u(N-1)] = \sum_{l=1}^{j-1} \lambda_{l}(N-1)r_{lj}(N-1)p(l|N-1) + \tau_{j}(N-2)u(N-1) + \tau_{j}(N-1)\alpha(N-1), j = 1,...,a$$
(21)

\_\_\_\_\_

The steady-state probabilities p(n) are obtained, as before, from (1). Note that equation (21) is similar to equation (4) except that it applies to n = N - 1. For n = 0, ..., N - 2, equation (3) applies as before. The probabilities upon arrival are given by formula (7). The probability that the source is blocked is simply p(N).

The blocking described above corresponds either to a closed network of two stations with a total population of N requests, or a node in a computer network with a buffer size of N packets where the source generating the packets is prevented from overflowing the buffer.
