

Training-free, Generic Object Detection using Locally Adaptive Regression Kernels

Abstract

We present a generic detection/localization algorithm capable of searching for a visual object of interest without training. The proposed method operates using a *single* example of an object of interest to find similar matches; does not require prior knowledge (learning) about objects being sought; and does not require any pre-processing step or segmentation of a target image. Our method is based on the computation of local regression kernels as descriptors from a query, which measure the likeness of a pixel to its surroundings. Salient features are extracted from said descriptors and compared against analogous features from the target image. This comparison is done using a matrix generalization of the cosine similarity measure. We illustrate optimality properties of the algorithm using a naive-Bayes framework. The algorithm yields a scalar resemblance map, indicating the likelihood of similarity between the query and all patches in the target image. By employing nonparametric significance tests and non-maxima suppression, we detect the presence and location of objects similar to the given query. The approach is extended to account for large variations in scale and rotation. High performance is demonstrated on several challenging datasets, indicating successful detection of objects in diverse contexts and under different imaging conditions.

Object detection, image representation, correlation and regression analysis

I. INTRODUCTION

Analysis of visual objects in images is a very important component in computer vision systems which perform object recognition, image retrieval, image registration, and more. Areas where such systems are deployed are diverse and include such applications as surveillance (security), video forensics, and medical image analysis for computer-aided diagnosis, to mention just a few. In particular, the object recognition problem has attracted much attention recently due to the increasing demand for developing real-world systems.

Recognition is mainly divided into two parts: category recognition (classification) and detection/localization [1]. The goal of object category recognition is to classify a given object into one of several pre-specified categories, while object detection is to separate objects of interest from the background in a target image. In the current literature, a popular object recognition paradigm is *probabilistic constellation* [2] or *parts-and-shape models* [3] that represent not only the statistics of individual parts, but also their spatial layout. These are based on learning-based classifiers, that require an intensive learning/training phase of the classifier parameters and thus are called parametric methods. Object detection is also a critical part in many applications such as image retrieval, scene understanding, and surveillance system; however it is still an open problem because the intra-class variation makes a generic detection very complicated, requiring various types of pre-processing steps. The sliding window scheme is usually used by taking the peak confidence values as an indication of the presence of an object in a given region. Most successful localization methods at the recent PASCAL VOC 2006 challenge [4] on object localization relied on this technique too, but these too still required a training phase. In order to make a real-time object detection system while achieving high detection rates, methods combining classifiers in a cascade [5], [6] have been proposed.

Recently, the recognition task with only one query (training-free) has received increasing attention [7], [8], [9], [10] for important applications such as automatic passport control at airports, where a single photo in the passport is the only example available. Another application is in image retrieval from the web [2], [7]. In the retrieval task, a single probe or query image is provided by users and every gallery image in the database is compared with the single probe, posing an image-to-image matching problem. Recently, the face image retrieval task led to intensive activity in this area, culminating in FRGC [11] (Face Recognition Grand Challenge). More generally, by taking into account a set of images which represents intra-class variations, more robust object recognition can be achieved. Such sets may consist of observations acquired from a video sequence or by multiple still shots. In other words, classifying an unknown set of images into one of the training classes can be achieved through set-to-image or set-to-set matching [10] without an intensive training phase. As a successful example of set-to-image matching, Boiman et al. [12] very recently showed that a trivial nearest-neighbor (NN) based image classifier in the space of the local image descriptors such as SIFT [13] and local self-similarity [7] is extremely simple, efficient and can even outperform the leading learning-based

image classifiers such as SVM-KNN [14], pyramid match kernel (PMK) [15], and more.

A. Problem Specification

Inspired by this trend toward training-free image analysis, this paper addresses the generic detection/localization problem of searching for an object of interest (for instance a picture of a face) within other “target” images with only a *single* “query” image. In order to avoid the disadvantages of learning-based methods which require a large amount of training examples, can result in over-fitting of parameters, and are generally slow in the training phase, we focus on a novel and sophisticated feature and a reliable similarity measure for comparing a collection of features.

In general, the target images may contain such similar objects (say other faces) but these will typically appear in completely different context and under different imaging conditions. Examples of such differences can range from rather simple optical or geometric differences (such as occlusion, differing view-points, lighting, and scale changes); to more complex inherent structural differences such as for instance a hand-drawn sketch of a face rather than a real face. As an example, we refer the reader to Fig. 3 (a). To date, many methods based on such features as histograms, gradients, and shape descriptors have been proposed to address this problem. We refer the interested reader to [16] and references therein for a good summary.

B. Overview of the Proposed Approach

In this paper, our contributions to the object detection task are two-fold. First, we propose to use local regression kernels as descriptors which capture the underlying local structure of the data exceedingly well, even in the presence of significant distortions. Second, we propose a novel approach to the detection problem using a non-parametric nearest-neighbor classifier, along with a generalization of the cosine similarity to the matrix case. The origin and motivation behind the use of these local kernels is the earlier work on adaptive kernel regression for image processing and reconstruction [17]. In that work, localized nonlinear filters were derived, which adapt themselves to the underlying structure of the image in order to very effectively perform denoising, interpolation, and deblurring [18]. The fundamental component of the so-called *steering* kernel regression method is the calculation of the local steering kernel (LSK) which essentially measures the local similarity of a pixel to its neighbors both geometrically and radiometrically. The

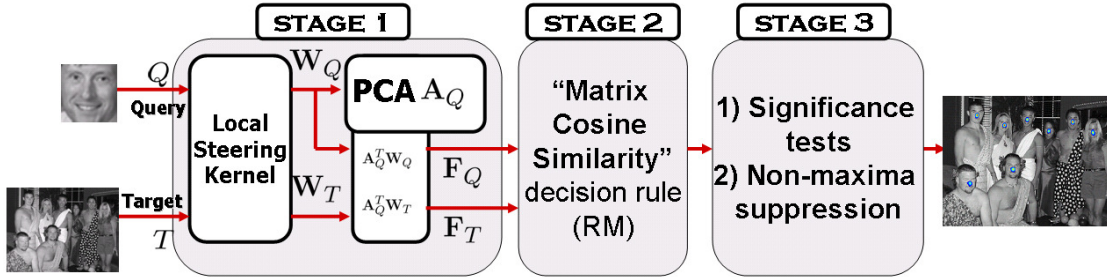

Fig. 1. System overview (There are broadly three stages.)

key idea is to robustly obtain local data structures by analyzing the radiometric (pixel value) differences based on estimated gradients, and use this structure information to determine the shape and size of a canonical kernel. Denoting the target image (T), and the query image (Q), we compute a dense set of local steering kernels from each. These densely computed descriptors are highly informative, but taken together tend to be over-complete (redundant). Therefore, we derive features by applying dimensionality reduction (namely PCA) to these resulting arrays, in order to retain only the salient characteristics of the local steering kernels. Generally, T is bigger than the query image Q . Hence, we divide the target image T into a set of overlapping patches which are the same size as Q and assign a class to each patch (T_i). The feature vectors which belong to a patch are thought of as training examples in the corresponding class (See Fig. 2). The feature collections from Q and T_i form feature matrices F_Q and F_{T_i} . We compare the feature matrices F_{T_i} and F_Q from i^{th} patch of T and Q to look for matches. Inspired in part by the many studies [19], [20], [21], [22], [23], [24] which took advantage of cosine similarity over the conventional Euclidean distance, we employ and justify the use of “Matrix Cosine Similarity” as a similarity measure which generalizes the cosine similarity between two vectors [25], [26], [27] to the matrix case. We illustrate the optimality properties of the proposed approach using a naive Bayes framework, which leads to the use of the Matrix Cosine Similarity (MCS) measure. Furthermore, we indicate how this measure can be efficiently implemented using a nearest-neighbor formulation. In order to deal with the case where the target image may not include any objects of interest or when there are more than one object in the target, we also adopt the idea of a significance test and non-maxima suppression [28].

Very recently, Shechtman and Irani [7] introduced a related matching framework based on the so-called “local self-similarity” descriptor. It is worth mentioning that this (independently derived) local self-similarity measure is a special case of the local steering kernel and is also

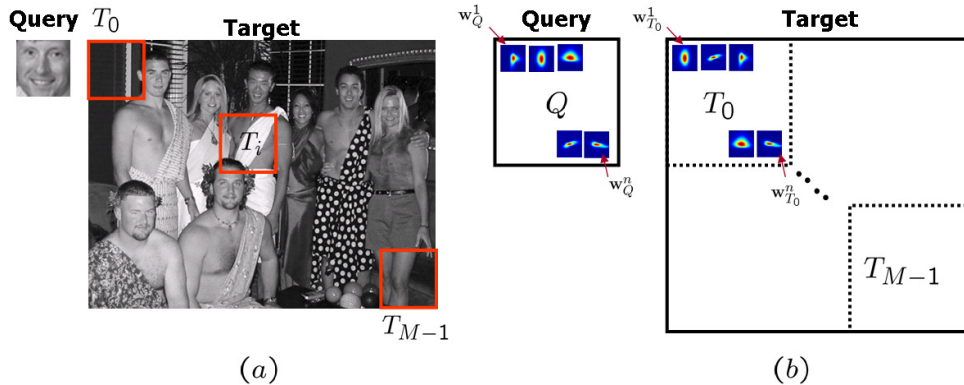

Fig. 2. (a) Given a query image Q , we want to detect/localize objects of interest in a target image T . T is divided into a set of overlapping patches (b) local steering kernels represent the geometric structure of underlying data.

related to a number of other local data adaptive metrics such as Optimal Spatial Adaptation (OSA) [29] and Non-Local Means (NLM) [30] which have been used for regression in the image processing community. While the local self-similarity descriptors in [7] were modeled as a function of a simple sum of squared difference (SSD) between a center image patch and surrounding image patches, local regression kernels are designed to have more sophisticated mechanisms to robustly obtain the local structure of images even in the presence of data uncertainty such as noise and blur. It is the aim of this paper to begin the process of applying the local regression kernel idea (in particular the local *steering* kernel) to problems involving detection of similarity across images, and later videos. It is worth noting that our contribution in this paper is intended in the same vain as the recent trend toward more extensive use of statistical signal processing and information theory, as nicely exemplified by the works [31], [32]. Fig. 1 shows an overview of our proposed framework. The first stage consists of computing the normalized LSKs $\mathbf{W}_Q, \mathbf{W}_T$ and obtaining the salient feature matrices $\mathbf{F}_Q, \mathbf{F}_T$. In the second stage, we compare the feature matrices \mathbf{F}_{T_i} and \mathbf{F}_Q using the Matrix Cosine Similarity measure. The final output is given after a sequence of significance tests, followed by non-maxima suppression [28]. Before we begin a more detailed description, it is worthwhile to highlight some aspects of the proposed framework.

- Since the calculation of local regression kernels is stable in the presence of uncertainty in the data [17], our approach is robust even in the presence of noise. In addition, normalized local regression kernels provide a certain invariance to illumination changes (see Fig. 4.)
- The approach in [7], similar to selective feature techniques such as SIFT [16] filters out “non-informative” descriptors, while in our method we apply Principal Components Analysis

(PCA) to a collection of LSKs in order to learn the most salient features of the data.

- While [7] explicitly models local and global geometric relationship between features, we simply propose to use “Matrix Cosine Similarity” which is a generalized version of the cosine similarity which has been shown to outperform the conventional Euclidean distance for subspace learning and classification tasks [19], [20], [21], [22], [23], [24]. We further propose “Canonical Cosine Similarity” in order to extend the proposed framework to the case of vector data such as a color image. As we shall see in Section IV-C, the Canonical Cosine Similarity is related to the concept of Canonical Correlation analysis [33].
- We employ the idea of nearest-neighbor classification [12] to solve the object detection problem and show that under the naive-Bayes assumption, theoretically optimal Bayes decision rule is approximated by the Matrix Cosine Similarity measure. This is in the same spirit as [21] which shows that the Bayes decision rule can be induced by the whitened cosine similarity under four strong assumptions.
- From a practical standpoint, it is important to note that the proposed framework operates using a single example of an image of interest to find similar matches; does not require any prior knowledge (learning) about objects being sought; and does not require any pre-processing step or segmentation of the target image.

The proposed framework is general enough as to be extendable to 3–D for such applications as action recognition [8], [10], suspicious behavior detection [34] etc. using an analogous 3–D local steering kernel [35]. The discussion of this aspect of the ongoing work is outside the scope of this paper. This paper is organized as follows. In the next section, we specify the algorithmic aspects of our object detection framework, using a novel feature (the “local *steering* kernel”) and a reliable similarity measure (the “Matrix Cosine Similarity”). Section III provides a theoretical formulation and justification of the proposed method. In Section IV, we extend the proposed method to more general scenarios, accounting for larger variations in scale and rotation, and for color images with the introduction of “Canonical Cosine Similarity”. In Section V, we demonstrate the performance of the system with some experimental results, and we conclude this paper in Section VI.

II. TECHNICAL DETAIL OF OBJECT DETECTION FRAMEWORK

As outlined in the previous section, our approach to detect objects consists broadly of three stages. Below, we describe each of these steps in detail.

A. Extracting Features from the Local Steering Kernel Descriptor

The key idea behind local steering kernel is to robustly obtain the local structure of images by analyzing the radiometric (pixel value) differences based on estimated gradients, and to use this structure information to determine the shape and size of a canonical kernel. The local kernel $K(\cdot)$ is modeled as a radially symmetric function.

$$K(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l) = \frac{K(\mathbf{H}_l^{-1}(\mathbf{x}_l - \mathbf{x}))}{\det(\mathbf{H}_l)}, \quad l = 1, \dots, P^2, \quad (1)$$

where $\mathbf{x}_l = [x_1, x_2]^T$ is the spatial coordinates, P^2 is the number of pixels in a local window ($P \times P$) and the so-called *steering* matrix is defined as

$$\mathbf{H}_l = h\mathbf{C}_l^{-\frac{1}{2}} \in \mathbb{R}^{(2 \times 2)}, \quad (2)$$

where h is a global smoothing parameter, and the matrix \mathbf{C}_l is a covariance matrix estimated from a collection of spatial (x_1, x_2) gradient vectors within the local analysis window around a sampling position \mathbf{x} . The *steering* matrix \mathbf{H}_l modifies the shape and size of the local kernel in a way which roughly encodes the local geometric structures present in the image (See Fig. 3 (b) for an example.) With such steering matrices, we choose a Gaussian function for $K(\cdot)$, which leads to the following form for the LSKs:

$$K(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l) = \frac{\sqrt{\det(\mathbf{C}_l)}}{2\pi h^2} \exp \left\{ -\frac{(\mathbf{x}_l - \mathbf{x})^T \mathbf{C}_l (\mathbf{x}_l - \mathbf{x})}{2h^2} \right\}. \quad (3)$$

We provide some discussion of this choice below, but for a more in depth analysis, we refer the interested reader to [17]. In what follows, at a position \mathbf{x} , we will essentially be using (a normalized version of) the function $K(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)$ as a function of \mathbf{x}_l and \mathbf{H}_l to represent

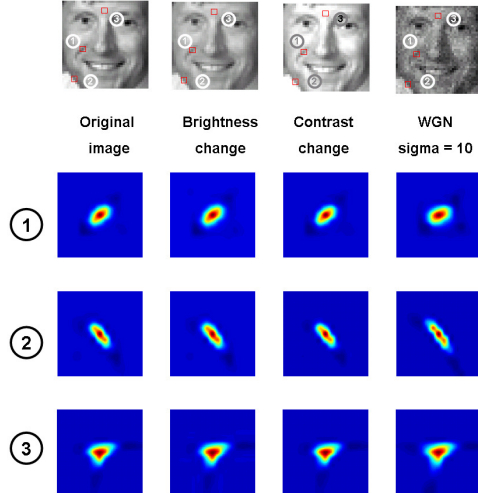

Fig. 4. Invariance and robustness of local *steering* kernel weights $W(\mathbf{x}_l - \mathbf{x}; 2)$ in various challenging conditions. Note that WGN means White Gaussian Noise.

an image’s inherent local geometry. To be more specific, the local steering kernel function $K^j(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)$ at a patch indexed by j is densely calculated and normalized as follows

$$\begin{aligned}
 W_Q^j(\mathbf{x}_l - \mathbf{x}) &= \frac{K_Q^j(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)}{\sum_{l=1}^{P^2} K_Q^j(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)}, \quad j = 1, \dots, n, \quad l = 1, \dots, P^2, \\
 W_T^j(\mathbf{x}_l - \mathbf{x}) &= \frac{K_T^j(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)}{\sum_{i=1}^{P^2} K_T^j(\mathbf{x}_l - \mathbf{x}; \mathbf{H}_l)}, \quad j = 1, \dots, n_T, \quad l = 1, \dots, P^2,
 \end{aligned} \tag{4}$$

where n and n_T are the number of patches where LSKs are computed in the query image Q and the target image T respectively ¹. Next, we describe some key properties of the above.

- Takeda et al. [17] showed that LSK based on the locally quadratic data model (regression order $N = 2$) consistently outperforms steering kernels based on the locally constant and the locally linear model (regression order $N = 0$ and $N = 1$) in their kernel regression framework for the tasks of image denoising and interpolation. They further provided the so-called “equivalent kernel” formulation which is a computationally more efficient and intuitive solution to kernel regression. To simplify the notation, we describe the normalized local steering kernels with the regression order N as $W(\mathbf{x}_l - \mathbf{x}; N)$. We observe that 2^{nd} order LSK $W(\mathbf{x}_l - \mathbf{x}; 2)$ provides better descriptive powers than 0^{th} order LSK $W(\mathbf{x}_l - \mathbf{x}; 0)$ and 1^{st} order LSK $W(\mathbf{x}_l - \mathbf{x}; 1)$ even in complex texture regions or in the presence of moderate levels of noise. Normalization of this kernel function yields invariance to brightness change and robustness to contrast change as shown in Fig. 4. When large amounts of noise are present, the locally quadratic data model

¹Note that images here are gray-scale (luminance channel only). In Section IV-C, we will deal with color images as well.

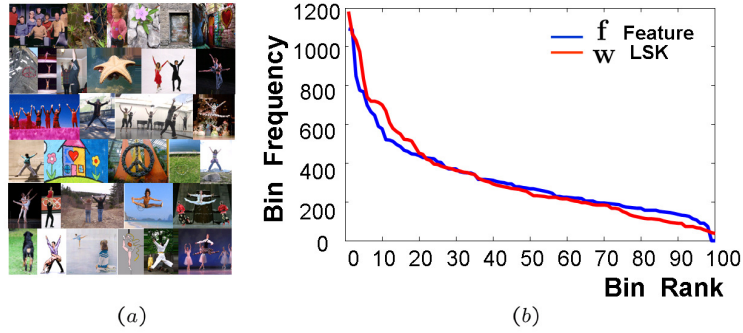

Fig. 5. (a) Some example images (Shechtman’s object dataset [7]) where LSKs were computed. (b) Plots of the bin density of LSKs and their corresponding low-dimensional features.

tends to be more sensitive to noise than the locally linear and the locally constant model. Hence, there is a trade-off between descriptive power of LSK and sensitivity to noise. Recently, Han and Vasconcelos [36] have proposed complex feature selection based on discriminant saliency for object classification. They showed that complex discriminant features tend to improve the performance of training-based image classifiers. Meanwhile, many studies [12], [37], [38] have shown that densely computed local image features give better results in classification tasks than key-point based local image features such as SIFT [13] which are designed for mainly invariance and compact coding. According to these studies, the distribution of the local image feature both in natural images as well as images of a specific object class follows a power-law (i.e., a long-tail) distribution [12], [37], [38]. In other words, the features are scattered out in a high dimensional feature space, and thus there basically exists no dense cluster in the feature space. In order to illustrate and verify that the normalized LSKs also satisfy this property as described in [7], [12] and follow a power-law distribution, we computed an empirical bin density (100 bins) of the normalized LSKs (using a total of 31,319 LSKs) densely computed from 60 images (from Shechtman’s general object dataset [7]) using the K-means clustering method (See Fig. 5 for an example.)

Boiman et al. [12] observed that while an ensemble of local features with little discriminative power can together offer a significant discriminative power, both quantization and informative feature selection on a long-tail distribution can lead to a precipitous drop in performance. Therefore, instead of any quantization and informative feature selection, we focus on reducing the dimension of densely computed LSKs using PCA to enhance the discriminative power and reduce computational complexity. It is worth noting that this approach was also taken by Ke et al. in [39] where PCA was applied to SIFT features, leading to enhanced performance. Ali and

Shah [40] also applied PCA to derive salient kinematic features from optical flow in the action recognition task. This idea results in a new feature representation with a moderate dimension which inherits the desirable discriminative attributes of LSK. The distribution of the resulting features sitting on the low dimensional manifold also tends to follow a power-law distribution as shown in Fig. 5 (b) and this attribute of the features will be utilized in applying a nearest-neighbor approximation in the theoretical formulation in Section III.

1) *Feature representation:* In order to organize $W_Q^j(\mathbf{x}_l - \mathbf{x})$ and $W_T^j(\mathbf{x}_l - \mathbf{x})$, which are densely computed from Q and T , let $\mathbf{W}_Q, \mathbf{W}_T$ be matrices whose columns are vectors $\mathbf{w}_Q^j, \mathbf{w}_T^j$, which are column-stacked (rasterized) versions of $W_Q^j(\mathbf{x}_l - \mathbf{x}), W_T^j(\mathbf{x}_l - \mathbf{x})$ respectively:

$$\mathbf{W}_Q = [\mathbf{w}_Q^1, \dots, \mathbf{w}_Q^n] \in \mathbb{R}^{P^2 \times n}, \quad \mathbf{W}_T = [\mathbf{w}_T^1, \dots, \mathbf{w}_T^{n_T}] \in \mathbb{R}^{P^2 \times n_T}. \quad (5)$$

As described in Fig. 1, the next step is to apply PCA² to \mathbf{W}_Q for dimensionality reduction and to retain only its salient characteristics. Applying PCA to \mathbf{W}_Q we can retain the first (largest) d principal components³ which form the columns of a matrix $\mathbf{A}_Q \in \mathbb{R}^{P^2 \times d}$. Next, the lower dimensional features are computed by projecting \mathbf{W}_Q and \mathbf{W}_T onto \mathbf{A}_Q :

$$\mathbf{F}_Q = [\mathbf{f}_Q^1, \dots, \mathbf{f}_Q^n] = \mathbf{A}_Q^T \mathbf{W}_Q \in \mathbb{R}^{d \times n}, \quad \mathbf{F}_T = [\mathbf{f}_T^1, \dots, \mathbf{f}_T^{n_T}] = \mathbf{A}_Q^T \mathbf{W}_T \in \mathbb{R}^{d \times n_T}. \quad (6)$$

Fig. 6 illustrates the principal components in \mathbf{A}_Q and shows what the features $\mathbf{F}_Q, \mathbf{F}_T$ look like for some examples such as face and car.

B. Matrix Cosine as a Measure of Similarity

The next step in the proposed framework is a decision rule based on the measurement of a “distance” between the computed features $\mathbf{F}_Q, \mathbf{F}_{T_i}$. Earlier works such as [19], [20], [24] have shown that correlation based metrics outperforms the conventional Euclidean and Mahalanobis distances for the classification and subspace learning tasks. Motivated by the effectiveness of correlation-based similarity measure, we introduce “Matrix Cosine Similarity” for the matrix case and explore the idea behind this measure in this section. In general, “correlation” indicates the strength and direction of a linear relationship between two random variables. But the idea of correlation is quite malleable. Indeed, according to Rodgers et al. [27], there are at least thirteen distinct ways to look at correlation! However, we are interested in two main types of correlation:

²It is worth noting that the use of the PCA here may not be critical in the sense that any unsupervised subspace learning method such as Kernel PCA, LLE [41], LPP [42] CDA [24], CPCA [19], and CEA [19] can be used.

³Typically, d is selected to be a small integer such as 3 or 4 so that 80 to 90% of the “information” in the LSKs would be retained. (i.e., $\frac{\sum_{i=1}^d \lambda_i}{\sum_{i=1}^{P^2} \lambda_i} \geq 0.8$ (to 0.9) where λ_i are the eigenvalues.)

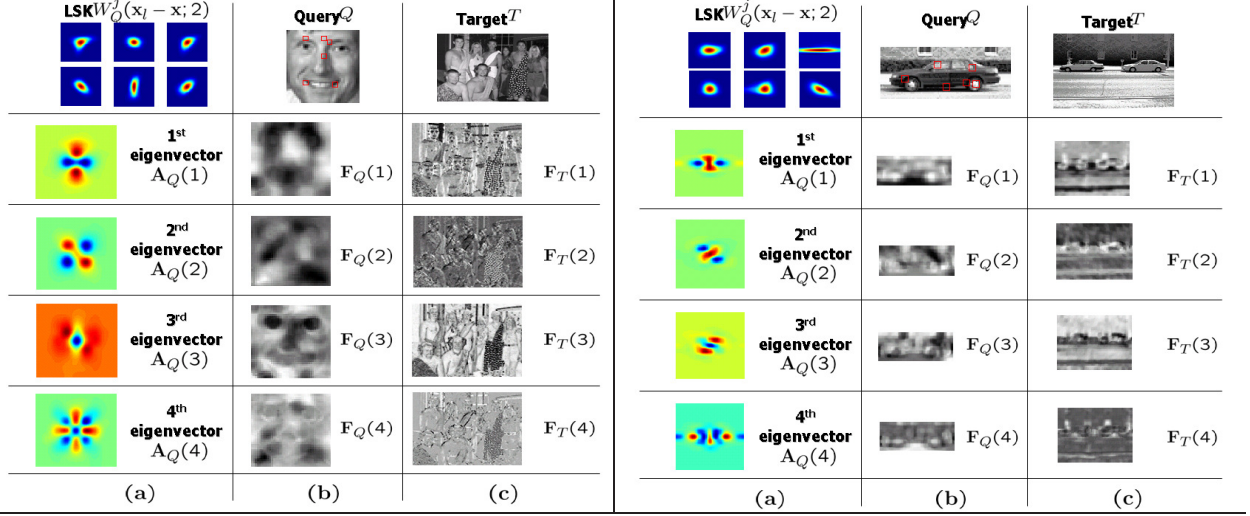

Fig. 6. Face and car examples (a) : \mathbf{A}_Q learned from a collection of LSKs \mathbf{W}_Q , (b): Feature row vectors of \mathbf{F}_Q from query Q , (c) : Feature row vectors \mathbf{F}_T from target image T . Eigenvectors and feature vectors were reshaped into image and up-scaled for illustration purposes.

The Pearson’s correlation coefficient which is the familiar standard correlation coefficient, and the cosine similarity (so-called non-Pearson-compliant). Note that the cosine similarity coincides with the Pearson’s correlation when each vector is centered to have zero-mean. In several earlier papers including [25], [26], it has been shown that the Pearson correlation is less discriminating than the cosine similarity due to the fact that centered values are less informative than the original values, and the computation of centered values is sensitive to zero or small values in the vectors. Since the discriminative power is critical in our detection framework, we focus on the cosine similarity. The cosine similarity is defined as the inner product between two normalized vectors as follows:

$$\rho(\mathbf{f}_Q, \mathbf{f}_{T_i}) = \left\langle \frac{\mathbf{f}_Q}{\|\mathbf{f}_Q\|}, \frac{\mathbf{f}_{T_i}}{\|\mathbf{f}_{T_i}\|} \right\rangle = \frac{\mathbf{f}_Q^T \mathbf{f}_{T_i}}{\|\mathbf{f}_Q\| \|\mathbf{f}_{T_i}\|} = \cos \theta_i \in [-1, 1], \quad (7)$$

where $\mathbf{f}_Q, \mathbf{f}_{T_i} \in \mathbb{R}^d$ are column vectors. The cosine similarity measure therefore focuses only on the angle (phase) information while discarding the scale information.

If we deal with the features $\mathbf{F}_Q, \mathbf{F}_{T_i}$ which consist of a set of vectors, “Matrix Cosine Similarity” can be defined as a natural generalization using the “Frobenius inner product” between two normalized matrices as follows:

$$\rho(\mathbf{F}_Q, \mathbf{F}_{T_i}) = \left\langle \overline{\mathbf{F}}_Q, \overline{\mathbf{F}}_{T_i} \right\rangle_F = \text{trace} \left(\frac{\mathbf{F}_Q^T \mathbf{F}_{T_i}}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F} \right) \in [-1, 1], \quad (8)$$

where, $\overline{\mathbf{F}}_Q = \frac{\mathbf{F}_Q}{\|\mathbf{F}_Q\|_F} = \left[\frac{\mathbf{f}_Q^1}{\|\mathbf{f}_Q^1\|_F}, \dots, \frac{\mathbf{f}_Q^n}{\|\mathbf{f}_Q^n\|_F} \right]$ and $\overline{\mathbf{F}}_{T_i} = \frac{\mathbf{F}_{T_i}}{\|\mathbf{F}_{T_i}\|_F} = \left[\frac{\mathbf{f}_{T_i}^1}{\|\mathbf{f}_{T_i}^1\|_F}, \dots, \frac{\mathbf{f}_{T_i}^n}{\|\mathbf{f}_{T_i}^n\|_F} \right]$.

It is worth noting that this generalization is also known as “vector correlation” in the statistics literature [43]. Fu et al. [19] also used a generalized cosine similarity to the tensor case for

subspace learning, and showed performance improvement in the task of image classification. Returning to our definition, if we look at Equation (8) carefully, it is interesting to note that one can rewrite it as a weighted average of the cosine similarities $\rho(\mathbf{f}_Q, \mathbf{f}_{T_i})$ between each pair of corresponding feature vectors (i.e., columns) in $\mathbf{F}_Q, \mathbf{F}_{T_i}$ as follows:

$$\rho(\mathbf{F}_Q, \mathbf{F}_{T_i}) = \sum_{\ell=1}^n \frac{\mathbf{f}_Q^{\ell T} \mathbf{f}_{T_i}^{\ell}}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F} = \sum_{\ell=1}^n \rho(\mathbf{f}_Q^{\ell}, \mathbf{f}_{T_i}^{\ell}) \frac{\|\mathbf{f}_Q^{\ell}\| \|\mathbf{f}_{T_i}^{\ell}\|}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F}. \quad (9)$$

The weights are represented as the product of $\frac{\|\mathbf{f}_Q^{\ell}\|}{\|\mathbf{F}_Q\|_F}$ and $\frac{\|\mathbf{f}_{T_i}^{\ell}\|}{\|\mathbf{F}_{T_i}\|_F}$ which indicate the relative importance of each feature in the feature sets $\mathbf{F}_Q, \mathbf{F}_{T_i}$. We see here an advantage of the ‘‘Matrix Cosine Similarity’’ in that it takes care of the strength and angle similarity of vectors at the same time. Hence, this measure not only generalizes the cosine similarity, but also overcomes the disadvantages of the conventional Euclidean distance which is sensitive to outliers. We compute $\rho(\mathbf{F}_Q, \mathbf{F}_{T_i})$ over all the target patches and this can be efficiently implemented by column-stacking the matrices $\mathbf{F}_Q, \mathbf{F}_{T_i}$ and simply computing the cosine similarity between two long column vectors as follows:

$$\begin{aligned} \rho_i \equiv \rho(\mathbf{F}_Q, \mathbf{F}_{T_i}) &= \sum_{\ell=1}^n \frac{\mathbf{f}_Q^{\ell T} \mathbf{f}_{T_i}^{\ell}}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F} = \sum_{\ell=1}^n \sum_{j=1}^d \frac{f_Q^{(\ell,j)} f_{T_i}^{(\ell,j)}}{\sqrt{\sum_{\ell=1}^n \sum_{j=1}^d |f_Q^{(\ell,j)}|^2} \sqrt{\sum_{\ell=1}^n \sum_{j=1}^d |f_{T_i}^{(\ell,j)}|^2}}, \\ &= \rho(\text{colstack}(\mathbf{F}_Q), \text{colstack}(\mathbf{F}_{T_i})) \in [-1, 1], \end{aligned} \quad (10)$$

where $f_Q^{(\ell,j)}, f_{T_i}^{(\ell,j)}$ are elements in ℓ^{th} vector \mathbf{f}_Q^{ℓ} and $\mathbf{f}_{T_i}^{\ell}$ respectively, and $\text{colstack}(\cdot)$ means an operator which column-stacks (rasterizes) a matrix.

In Section IV, we will show that this idea enables us to further generalize the cosine similarity to a ‘‘Canonical Cosine Similarity’’ which is a corresponding version of the canonical correlation analysis (CCA) [33] for the vector data case where we have a set of features separately computed from multiple sources (for instance, color image (YCbCr or CIE L*a*b*) or a sequence of images). In a similar vein as Boiman et al. [12], we will show in Section III that a particular version of optimal Naive-Bayes decision rule can actually lead to the use of ‘‘Matrix Cosine Similarity’’ (MCS) measure.

The next step is to generate a so-called ‘‘resemblance map’’ (RM), which will be an image with values indicating the likelihood of similarity between the Q and T . When it comes to interpreting the value of ‘‘correlation’’, it is noted in [44], [45] that $\rho_i^2 \in [0, 1]$ describes the proportion of variance in common between the two feature sets as opposed to ρ_i which indicates a linear relationship between two feature matrices $\mathbf{F}_Q, \mathbf{F}_{T_i}$. At this point, we can use ρ_i directly as a measure of resemblance between the two feature sets. However, the shared variance interpretation of ρ_i^2 has several advantages. In particular, as for the final test statistic comprising the values

Fig. 7. (a) Resemblance map (RM) which consists of $|\rho_i|$ (b) Resemblance map (RM) which consists of $f(\rho_i)$. Note that Q and T are the same examples shown in Fig 2.

in the resemblance map, we use the *proportion* of shared variance (ρ_i^2) to that of the “residual” variance ($1 - \rho_i^2$). More specifically, RM is computed using the mapping function f as follows:

$$\text{RM} : f(\rho_i) = \frac{\rho_i^2}{1 - \rho_i^2}. \quad (11)$$

In Fig. 7, examples of resemblance map (RM) based on $|\rho_i|$ and $f(\rho_i)$ are presented. Red color represents higher resemblance. As is apparent from these typical results, qualitatively, the resemblance map generated from $f(\rho_i)$ provides better contrast and dynamic range in the result ($f(\rho_i) \in [0, \infty]$). More importantly, from a quantitative point of view, we note that $f(\rho_i)$ is essentially the Lawley-Hotelling Trace statistic [33], [46], which is used as an efficient test statistic for detecting correlation between two data sets. Furthermore, it is worth noting that historically, this statistic has been suggested in the pattern recognition literature as an effective means of measuring the separability of two data clusters (e.g. [47].)

C. Non-Parametric Significance Test and Non-Maxima Suppression

If the task is to find the most similar patch (T_i) to the query (Q) in the target image, one can choose the patch which results in the largest value in the RM (i.e., $\max f(\rho_i)$) among all the patches, no matter how large or small the value is in the range of $[0, \infty]$. This, however, is not wise because there may not be *any* object of interest present in the target image. We are therefore interested in two types of significance tests. The first is an overall test to decide whether there is any sufficiently similar object present in the target image at all. If the answer is yes, we would then want to know how many objects of interest are present in the target image and where they are. Therefore, we need two thresholds: an overall threshold τ_o and a threshold τ to detect the possibly multiple objects present in the target image.

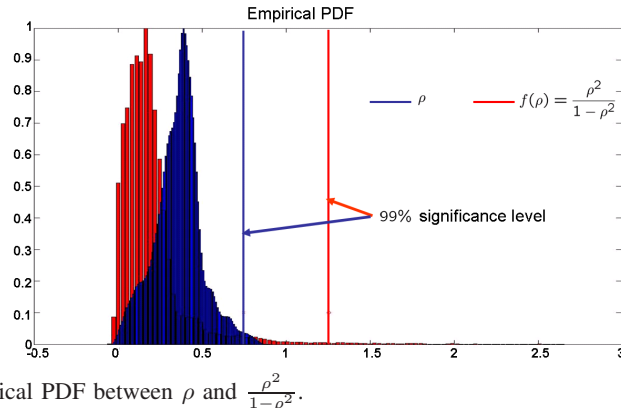

Fig. 8. Comparison of empirical PDF between ρ and $\frac{\rho^2}{1-\rho^2}$.

In a typical scenario, we set the overall threshold τ_o to be, for instance, 0.96 which is about 50% of variance in common (i.e., $\rho^2 = 0.49$). In other words, if the maximal $f(\rho_i)$ is just above 0.96, we decide that there exists at least one object of interest. The next step is to choose τ based on the properties of $f(\rho_i)$. When it comes to choosing the τ , there is need to be more careful. If we have a basic knowledge of the underlying distribution of $f(\rho_i)$, then we can make predictions about how this particular statistic will behave, and thus it is relatively easy to choose a threshold which will indicate whether the pair of features from the two images are sufficiently similar. But, in practice, we do not have a very good way to model the distribution of $f(\rho_i)$. Therefore, instead of assuming a type of underlying distribution, we employ the idea of nonparametric testing. We compute an empirical PDF from all the give samples of $f(\rho_i)$ and we set τ so as to achieve, for instance, a 99 % confidence level in deciding whether the given values are in the extreme (right) tails of the distribution ⁴. This approach is based on the assumption that in the target image, most of patches do not contain the object of interest, and therefore, the few matches will result in values which are in the tails of the distributions of $f(\rho_i)$. After the two significance tests with τ_o, τ are performed, we employ the idea of non-maxima suppression [28] for the final detection. We take the region with the highest $f(\rho_i)$ value and eliminate the possibility that any other object is detected within some radius ⁵ of the center of that region again. This enables us to avoid multiple false detections of nearby objects already detected. Then we iterate this process until the local maximum value falls below the threshold τ . Fig. 9 shows the graphical illustration of significance tests and the non-maxima suppression idea.

⁴Yet another justification for using $f(\rho_i)$ instead of ρ_i is the observation that the empirical PDF of ρ_i is itself heavy-tailed, making the detection of rare events more difficult. The use of $f(\rho_i)$ instead tends to alleviate this problem (see Fig. 8.)

⁵The size of this “exclusion” region will depend on the application at hand and the characteristics of the query image

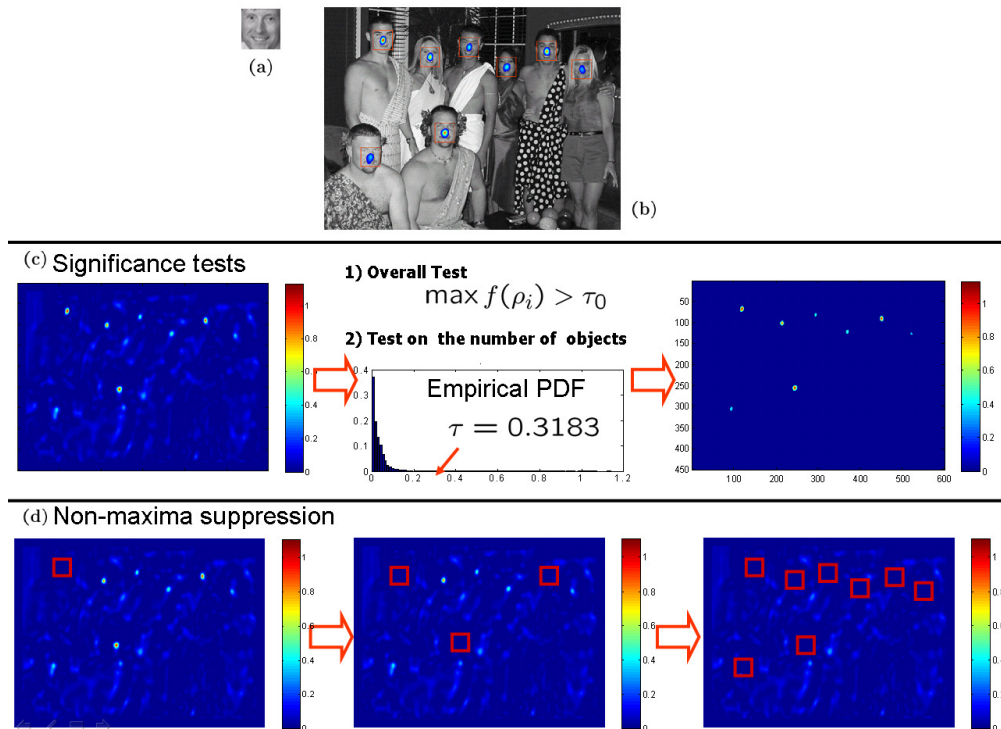

Fig. 9. (a) Query (b) Target with detection (c) Two significance tests (d) Non-maxima suppression [28]

III. THEORETICAL JUSTIFICATION

As explained in the previous section, the purpose of the proposed framework is to detect an object (or objects) of interest in the target image given a *single* query. In this section, we show that the naive-Bayes approach in a multiple hypothesis testing framework leads to the Matrix Cosine Similarity-based decision rule. It is worth noting that this idea is partly motivated by [12] and [21] who derived optimal Bayes decision rule based on Euclidean distance and the whitened cosine similarity respectively for the image classification task.

As described earlier, the target image T is divided into a set of overlapping patches and a class is assigned to each patch. Our task at hand is to figure out which class (i) the features from Q are most likely to have come from. Since we do not know the class-conditional pdf ($p(\overline{\mathbf{F}}_Q|class)$) of the normalized features extracted from Q , we set out to estimate it using a kernel density estimation method [48]. Once we have these estimates, we will show that the maximum likelihood (ML) decision rule boils down to computing and thresholding Matrix Cosine Similarity, which can be efficiently implemented using a nearest neighbor formulation.

By associating each patch (T_i) of the target image with a hypothesis, we now have the case where we wish to discriminate between M hypotheses ($\mathcal{H}_0, \dots, \mathcal{H}_{M-1}$) as follows:

$$\begin{aligned}
\mathcal{H}_0: & \quad Q \text{ is similar to } T_0 \Leftrightarrow \bar{\mathbf{F}}_Q \text{ comes from class 0 } (\bar{\mathbf{F}}_{T_0}), \\
\mathcal{H}_1: & \quad Q \text{ is similar to } T_1 \Leftrightarrow \bar{\mathbf{F}}_Q \text{ comes from class 1 } (\bar{\mathbf{F}}_{T_1}), \\
& \quad \vdots \\
& \quad \vdots \\
\mathcal{H}_{M-1}: & \quad Q \text{ is similar to } T_{M-1} \Leftrightarrow \bar{\mathbf{F}}_Q \text{ comes from class } M-1 (\bar{\mathbf{F}}_{T_{M-1}}).
\end{aligned}$$

The task at hand is to find the most likely hypothesis (or a correct class) given the query image Q . It is a well known fact [47], [49] that maximizing a posteriori probability $P(\mathcal{H}_i|\bar{\mathbf{F}}_Q)$ minimizes Bayes risk (or the average classification error.) Assuming that the prior probabilities $P(\mathcal{H}_i)$ are equal, then the maximum a posterior (MAP) decision rule boils down to the M-ary maximum likelihood (ML) decision rule.

$$\hat{\mathcal{H}}_i = \arg \max_i P(\mathcal{H}_i|\bar{\mathbf{F}}_Q) = \arg \max_i p(\bar{\mathbf{F}}_Q|\mathcal{H}_i). \quad (12)$$

Since we do not know the conditional probability density function $p(\bar{\mathbf{F}}_Q|\mathcal{H}_i)$ of features $\bar{\mathbf{F}}_Q$ given the features $\bar{\mathbf{F}}_{T_i}$ of the target patch T_i , we need to estimate it using a kernel density estimation method, which results in the naive or empirical Bayes approach.

A. Locally Data-adaptive Kernel Density Estimation

The Parzen density estimator is a simple and generally accurate non-parametric density estimation method [48]. However, if the true conditional density that we want to model is close to a “non-linear” lower dimensional manifold embedded in the higher dimensional feature space, Parzen density estimator with an isotropic kernel is not the most appropriate method [50], [51], [52]. As explained earlier, the features $\bar{\mathbf{F}}_Q, \bar{\mathbf{F}}_{T_i}$ tend to generically come from long-tailed distributions, and as such, there are generally no tight clusters in the feature space. When we estimate a probability density at a particular point, for instance $\bar{\mathbf{F}}_Q^\ell$, the isotropic kernel centered on that point will spread its density mass equally along all the feature space directions, thus giving too much emphasis to irrelevant regions of space and too little along the manifold. Earlier studies [50], [51], [52] also pointed out this problem. This motivates us to use *a locally data-adaptive version of the kernel density estimator*.

The estimated conditional density $\hat{p}(\bar{\mathbf{F}}_Q|\mathcal{H}_i)$ is defined as a sum of kernels (weight functions) centered at the features $\bar{\mathbf{f}}_{T_i}$ in T_i which belong to the hypothesis \mathcal{H}_i . More specifically,

$$\hat{p}(\bar{\mathbf{F}}_Q|\mathcal{H}_i) = \frac{\sum_{j=1}^n K^j(\bar{\mathbf{F}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j)}{\sum_{\ell \in \Omega_Q} \sum_{j=1}^n K^j(\bar{\mathbf{F}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j)}, \quad \ell \in \Omega_Q, \quad (13)$$

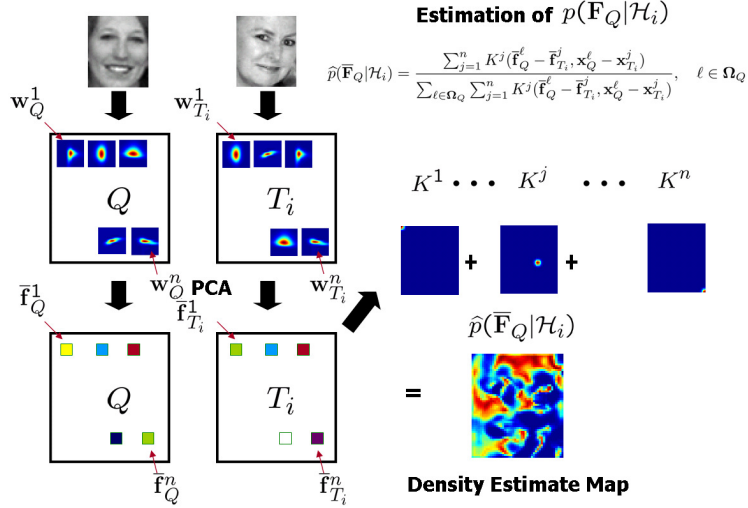

Fig. 10. The estimated conditional density $\hat{p}(\bar{\mathbf{F}}_Q | \mathcal{H}_i)$ is a sum of kernels (weight functions) centered at the features $\bar{\mathbf{f}}_{T_i}$ in T_i which belongs to the hypothesis \mathcal{H}_i . In the Density Estimate Map, red value means a high conditional probability density $\hat{p}(\bar{\mathbf{f}}_Q | \mathcal{H}_i)$ while blue value represents a low conditional probability density $\hat{p}(\bar{\mathbf{f}}_Q | \mathcal{H}_i)$.

where K^j is a locally data adaptive kernel function, Ω_Q is the query image domain consisting of $|\Omega_Q|$ pixels and $\mathbf{x}_Q^\ell, \mathbf{x}_{T_i}^j$ are column vectors denoting spatial coordinates of corresponding features $\bar{\mathbf{f}}_Q^\ell$ and $\bar{\mathbf{f}}_{T_i}^j$. A simple and intuitive choice of the K^j is to consider two terms for penalizing the spatial distance between the point of interest and its neighbors, and the radiometric “distance” between the corresponding features $\bar{\mathbf{f}}_Q^\ell$ and $\bar{\mathbf{f}}_{T_i}^j$. More specifically, the kernel function is defined as follows:

$$\begin{aligned} K^j(\bar{\mathbf{f}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j) &= K_r^j(\bar{\mathbf{f}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j) K_s^j(\mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j), \\ &= \exp\left(-\frac{1}{2\sigma_r^2} \text{dist}(\bar{\mathbf{f}}_Q^\ell, \bar{\mathbf{f}}_{T_i}^j)\right) \exp\left(-\frac{1}{2\sigma_s^2} \|\mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j\|^2\right), \quad \ell \in \Omega_Q, \end{aligned} \quad (14)$$

where we define $\text{dist}(\bar{\mathbf{f}}_Q^\ell, \bar{\mathbf{f}}_{T_i}^j) = \left\| \frac{\mathbf{f}_Q^\ell}{\|\mathbf{F}_Q\|_F} - \frac{\mathbf{f}_{T_i}^j}{\|\mathbf{F}_{T_i}\|_F} \right\|^2$, and σ_r, σ_s are parameters controlling the fall-off of weights in radiometric and spatial domains.

Inserting equation (14) into equation (13), the estimated conditional density $\hat{p}(\bar{\mathbf{F}}_Q | \mathcal{H}_i)$ becomes

$$\hat{p}(\bar{\mathbf{F}}_Q | \mathcal{H}_i) = \frac{1}{\beta} \sum_{j=1}^n \exp\left(-\frac{1}{2\sigma_r^2} \text{dist}(\bar{\mathbf{f}}_Q^\ell, \bar{\mathbf{f}}_{T_i}^j)\right) \exp\left(-\frac{1}{2\sigma_s^2} \|\mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j\|^2\right), \quad \ell \in \Omega_Q, \quad (15)$$

where β is a normalization factor ($\beta = \sum_{\ell \in \Omega_Q} \sum_{j=1}^n K^j(\bar{\mathbf{f}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j)$). Fig. 10 depicts how the conditional density function $\hat{p}(\bar{\mathbf{F}}_Q | \mathcal{H}_i)$ is estimated, given Q and T_i .

In principle, all n features should be employed to obtain an accurate density estimation. However, this is too computationally time-consuming. Hence, as we describe next, we use an efficient approximation of this locally data-adaptive kernel density estimator.

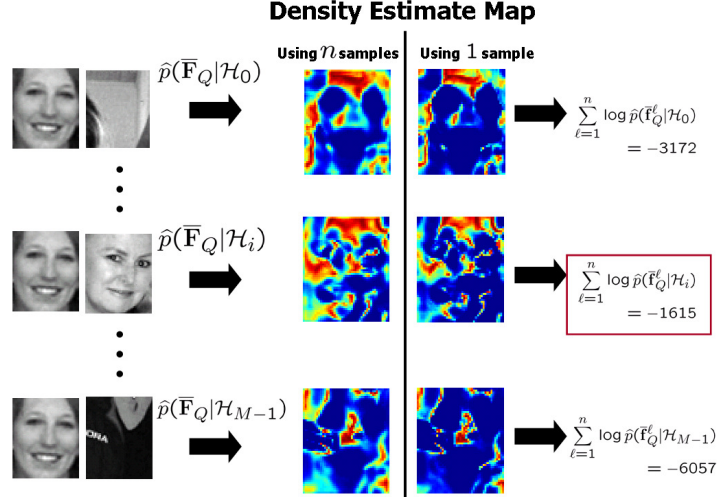

Fig. 11. The estimated conditional probability densities $\hat{p}(\bar{\mathbf{F}}_Q|\mathcal{H}_i)$ using n samples and 1 sample are shown in the middle and the scores on right side means $\sum_{\ell=1}^n \log \hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i)$. The higher this score is, the more likely $\bar{\mathbf{F}}_Q$ comes from class i ($\bar{\mathbf{F}}_{T_i}$)

B. Approximation of Locally Data-adaptive Kernel Density

Assuming that $\bar{\mathbf{f}}_Q^1, \bar{\mathbf{f}}_Q^2, \dots, \bar{\mathbf{f}}_Q^n$ are i.i.d. given hypothesis \mathcal{H}_i , the ML decision rule can be rewritten by taking the log probability of the ML decision rule (12) as:

$$\hat{\mathcal{H}}_i = \arg \max_i \log \hat{p}(\bar{\mathbf{F}}_Q|\mathcal{H}_i) = \arg \max_i \log \hat{p}(\bar{\mathbf{f}}_Q^1, \dots, \bar{\mathbf{f}}_Q^n|\mathcal{H}_i) = \arg \max_i \sum_{\ell=1}^n \log \hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i). \quad (16)$$

What we do next is to estimate each local individual probability density $\hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i)$ separately:

$$\hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i) = \frac{1}{\beta'} \sum_{j=1}^n K^j(\bar{\mathbf{f}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j), \quad \ell = 1, \dots, n, \quad (17)$$

where β' is a normalization factor ($\beta' = \sum_{\ell=1}^n \sum_{j=1}^n K^j(\bar{\mathbf{f}}_Q^\ell - \bar{\mathbf{f}}_{T_i}^j, \mathbf{x}_Q^\ell - \mathbf{x}_{T_i}^j)$). As nicely motivated in [12] and discussed in Section II-A, since the distribution of the features on the low-dimensional manifold tends to follow a power-law (i.e., long-tail or heavy-tail), it should be sufficient to use just a few features in T_i to get a reasonable estimate of the conditional density $\hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i)$. Therefore, we consider using a single (spatially nearest) neighbor for the approximation, which yields:

$$\begin{aligned} \hat{p}(\bar{\mathbf{f}}_Q^\ell|\mathcal{H}_i) &\approx \exp\left(-\frac{1}{2\sigma_r^2} \text{dist}(\bar{\mathbf{f}}_Q^\ell, \bar{\mathbf{f}}_{T_i}^\ell)\right), \\ &= \exp\left(-\frac{1}{2\sigma_r^2} \left(\frac{\|\mathbf{f}_Q^\ell\|^2}{\|\bar{\mathbf{F}}_Q\|_F^2} + \frac{\|\mathbf{f}_{T_i}^\ell\|^2}{\|\bar{\mathbf{F}}_{T_i}\|_F^2} - 2\rho(\mathbf{f}_Q^\ell, \mathbf{f}_{T_i}^\ell) \frac{\|\mathbf{f}_Q^\ell\| \|\mathbf{f}_{T_i}^\ell\|}{\|\bar{\mathbf{F}}_Q\|_F \|\bar{\mathbf{F}}_{T_i}\|_F}\right)\right), \quad \ell = 1, \dots, n. \end{aligned} \quad (18)$$

The approximate version of density estimator using one sample is compared to $\hat{p}(\bar{\mathbf{F}}_Q|\mathcal{H}_i)$ estimated using all n samples in Fig. 11. Qualitatively, we observe that the resulting estimates are quite similar. More precisely, consistent with [12], we have verified that the use of the

Algorithm 1 Pseudo-code for the non-parametric object detection algorithm

Q : Query image, T : Target image, τ_o : Overall threshold, α : Confidence level, P^2 : Size of local steering kernel (LSK) window.

Stage1 : Feature representation

- 1) Construct $\mathbf{W}_Q, \mathbf{W}_T$ which are a collection of normalized LSK associated with Q, T .
- 2) Apply PCA to \mathbf{W}_Q and obtain projection space \mathbf{A}_Q from its top d eigenvectors.
- 3) Project \mathbf{W}_Q and \mathbf{W}_T onto \mathbf{A}_Q to construct \mathbf{F}_Q and \mathbf{F}_T .

Stage2 : Compute Matrix Cosine Similarity

for every target patch T_i , where $i \in [0, \dots, M-1]$ do

$$\rho_i = \langle \frac{\mathbf{F}_Q}{\|\mathbf{F}_Q\|_F}, \frac{\mathbf{F}_{T_i}}{\|\mathbf{F}_{T_i}\|_F} \rangle_F \text{ and compute resemblance map (RM) : } f(\rho_i) = \frac{\rho_i^2}{1-\rho_i^2}.$$

end for

Then, find $\max f(\rho_i)$.

Stage3 : Significance tests and Non-maxima suppression

- 1) If $\max f(\rho_i) > \tau_o$, go on to the next test. Otherwise, there is no object of interest in T .
 - 2) Threshold RM by τ which is set to achieve 99 % confidence level ($\alpha = 0.99$) from the empirical PDF of $f(\rho_i)$.
 - 3) Apply non-maxima suppression to RM until the local maximum value is below τ .
-

approximation takes little away from the performance of the overall algorithm, which is discussed in Section II-A.

Since $\log \widehat{p}(\widehat{\mathbf{f}}_Q^\ell | \mathcal{H}_i)$ is approximately proportional to $-\left(\frac{\|\mathbf{f}_Q^\ell\|^2}{\|\mathbf{F}_Q\|_F^2} + \frac{\|\mathbf{f}_{T_i}^\ell\|^2}{\|\mathbf{F}_{T_i}\|_F^2} - 2\rho(\mathbf{f}_Q^\ell, \mathbf{f}_{T_i}^\ell) \frac{\|\mathbf{f}_Q^\ell\| \|\mathbf{f}_{T_i}^\ell\|}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F}\right)$, the ML decision rule becomes

$$\begin{aligned} \widehat{\mathcal{H}}_i &= \arg \max_i \sum_{\ell=1}^n \log \widehat{p}(\widehat{\mathbf{f}}_Q^\ell | \mathcal{H}_i) \Rightarrow \arg \max_i \sum_{\ell=1}^n -\left(\frac{\|\mathbf{f}_Q^\ell\|^2}{\|\mathbf{F}_Q\|_F^2} + \frac{\|\mathbf{f}_{T_i}^\ell\|^2}{\|\mathbf{F}_{T_i}\|_F^2} - 2\rho(\mathbf{f}_Q^\ell, \mathbf{f}_{T_i}^\ell) \frac{\|\mathbf{f}_Q^\ell\| \|\mathbf{f}_{T_i}^\ell\|}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F}\right), \\ &= \arg \max_i \left(-2 + 2 \sum_{\ell=1}^n \frac{\mathbf{f}_Q^{\ell T} \mathbf{f}_{T_i}^\ell}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F}\right), \\ &= \arg \max_i \sum_{\ell=1}^n \frac{\mathbf{f}_Q^{\ell T} \mathbf{f}_{T_i}^\ell}{\|\mathbf{F}_Q\|_F \|\mathbf{F}_{T_i}\|_F} = \arg \max_i \left\langle \frac{\mathbf{F}_Q}{\|\mathbf{F}_Q\|_F}, \frac{\mathbf{F}_{T_i}}{\|\mathbf{F}_{T_i}\|_F} \right\rangle_F. \end{aligned} \quad (19)$$

We can clearly see that the ML decision rule in Equation (19) boils down to the computation of the Matrix Cosine Similarity, due to the relationship $\left\langle \frac{\mathbf{F}_Q}{\|\mathbf{F}_Q\|_F}, \frac{\mathbf{F}_{T_i}}{\|\mathbf{F}_{T_i}\|_F} \right\rangle_F \approx \frac{2 + \sum_{\ell=1}^n \log \widehat{p}(\widehat{\mathbf{f}}_Q^\ell | \mathcal{H}_i)}{2}$. While the assumptions leading to the above conclusions may seem somewhat restrictive, in practice they appear to hold true, and they do provide a framework in which the proposed algorithm can be considered optimal in the naive Bayes sense. Indeed, as can be seen from the practical experimental results in Section V, the range of applicability of the algorithm thus justified is quite wide. To summarize, the overall pseudo-code for the algorithm is given in **Algorithm 1**.

IV. HANDLING VARIATIONS IN SCALE AND ROTATION, AND COLOR IMAGES

Up to now, we only dealt with the detection of objects in a gray image at a single scale. Although our detection framework can handle modest scale and rotation variations by adopting a sliding window scheme, robustness to larger scale and rotation changes (for instance above $\pm 20\%$ in scale, 30 degrees in rotation) are desirable. Furthermore, the use of color images as input should be also considered from a practical point of view. In this section, the approach described in the previous sections for detecting objects at a single scale is extended to detect objects at different scales and at different orientations in an image. In addition, we deal with a color image by defining and using ‘‘Canonical Cosine Similarity’’.

A. Multi-Scale approach

In order to cope with large scale variations, we construct a multi-scale pyramid of the target image T . This is a non-standard pyramid as we reduce the target image size by steps of $10 \sim 15\%$, so that a relatively fine quantization of scales are taken into account. Fig. 12 (a) shows the block diagram of the multi-scale approach. The first step is to construct the multi-scale pyramid T^0, T^1, \dots, T^S where S is the coarsest scale of the pyramid. As shown in Fig. 12 (a), $\mathbf{F}_Q, \mathbf{F}_{T^0}, \mathbf{F}_{T^1}, \mathbf{F}_{T^2} (S = 2)$ are obtained by projecting \mathbf{W}_Q and $\mathbf{W}_{T^0}, \mathbf{W}_{T^1}, \mathbf{W}_{T^2}$ onto the principal subspace defined by \mathbf{A}_Q as follows:

$$\mathbf{F}_Q = \mathbf{A}_Q^T \mathbf{W}_Q, \quad \mathbf{F}_{T^0} = \mathbf{A}_Q^T \mathbf{W}_{T^0}, \quad \mathbf{F}_{T^1} = \mathbf{A}_Q^T \mathbf{W}_{T^1}, \quad \mathbf{F}_{T^2} = \mathbf{A}_Q^T \mathbf{W}_{T^2}. \quad (20)$$

We obtain three resemblance maps $\text{RM}_0, \text{RM}_1, \text{RM}_2$ by computing $f(\rho_i) = \frac{\rho_i^2}{1-\rho_i^2}$. These resemblance maps represent the likelihood functions $p(f(\rho_i)|S_i)$ where S_i is the scale at i^{th} point. However the sizes of the respective resemblance maps $\text{RM}_0, \text{RM}_1, \text{RM}_2$ are naturally different. Therefore, we simply upscale all the resemblance maps by pixel replication so that they match the dimensions of the finest scale map RM_0 . Next, the maximum likelihood estimate of the scale at each position is arrived at by comparing the upscaled resemblance maps as follows ⁶:

$$\hat{S}_i = \arg \max_{S_i} p(\underline{\text{RM}}|S_i). \quad (21)$$

B. Multi-Rotation approach

In order to cope with large rotations, we take a similar approach and generate rotated images (this time of the query image Q) in roughly 30 degree steps. As seen in Fig. 12 (b),

⁶By $\underline{\text{RM}}$ we mean a collection of RM indexed by i at each position.

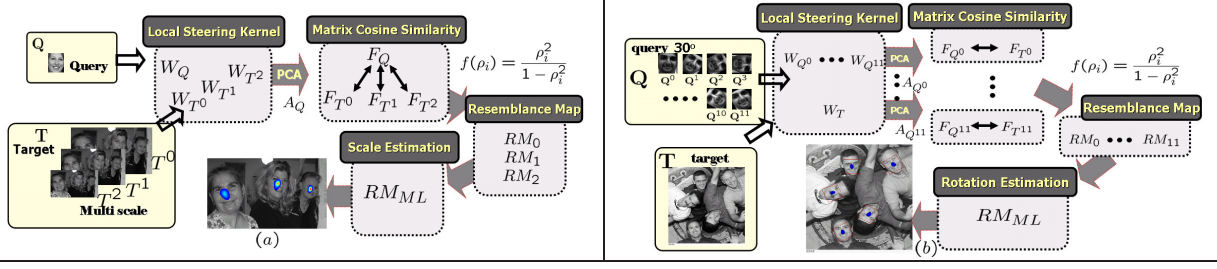

Fig. 12. (a) Block diagram of multi-scale object detection system, (b) Block diagram of multi-rotation object detection system

$\mathbf{F}_{Q^0}, \mathbf{F}_{Q^1}, \dots, \mathbf{F}_{Q^{11}}$ and \mathbf{F}_T are obtained by projecting $\mathbf{W}_{Q^0}, \dots, \mathbf{W}_{Q^{11}}$ and \mathbf{W}_T onto the principal subspace defined by $\mathbf{A}_{Q^0}, \dots, \mathbf{A}_{Q^{11}}$. After computing $f(\rho_i) = \frac{\rho_i^2}{1 - \rho_i^2}$ from 12 pairs by employing the sliding window scheme, we obtain twelve resemblance maps $\text{RM}_0, \dots, \text{RM}_{11}$. We compute the maximum likelihood estimate of the best matching pattern accounting for rotation as follows:

$$\hat{R}_i = \arg \max_{R_i} p(\text{RM} | R_i). \quad (22)$$

C. Canonical Cosine Similarity

Now, we define Canonical Cosine Similarity (CCS) to extend the proposed framework with a single gray-scale query image to vector-valued images. In particular, suppose at each pixel, the image has q values. As per the earlier discussion (Section II-B), we generate q feature sets $\mathbf{F}_Q^\ell, \mathbf{F}_{T_i}^\ell (\ell = [1, \dots, q])$ by projecting $\mathbf{W}_Q^\ell, \mathbf{W}_{T_i}^\ell$ onto the subspaces \mathbf{A}_Q^ℓ respectively and form the overall feature set as follows:

$$\mathbf{F}_I = [\text{colstack}(\mathbf{F}_I^1), \dots, \text{colstack}(\mathbf{F}_I^q)] \in \mathbb{R}^{(d \times n) \times q}, I \in \{Q, F_i\}. \quad (23)$$

The key idea is to find the vectors \mathbf{u}_Q and \mathbf{u}_{T_i} which maximally correlate two data sets $(\mathbf{F}_Q, \mathbf{F}_{T_i})$.

$$\mathbf{v}_I = \mathbf{F}_I \mathbf{u}_I = u_{I_1} \text{colstack}(\mathbf{F}_I^1) + \dots + u_{I_q} \text{colstack}(\mathbf{F}_I^q) \in \mathbb{R}^{(d \times n)}, I \in \{Q, F_i\}, \quad (24)$$

where $\mathbf{u}_Q = [u_{Q_1}, \dots, u_{Q_q}]^T \in \mathbb{R}^q$ and $\mathbf{u}_{T_i} = [u_{T_i_1}, \dots, u_{T_i_q}]^T \in \mathbb{R}^q$.

Then, the objective function we are maximizing is the cosine similarity between \mathbf{d}_Q and \mathbf{d}_{T_i} as follows.

$$\rho = \max_{\mathbf{u}_Q, \mathbf{u}_{T_i}} \frac{\mathbf{v}_Q^T \mathbf{v}_{T_i}}{\|\mathbf{v}_Q\| \|\mathbf{v}_{T_i}\|} = \max_{\mathbf{u}_Q, \mathbf{u}_{T_i}} \frac{\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_{T_i} \mathbf{u}_{T_i}}{\|\mathbf{F}_Q \mathbf{u}_Q\| \|\mathbf{F}_{T_i} \mathbf{u}_{T_i}\|}, \quad \text{such that } \|\mathbf{F}_Q \mathbf{u}_Q\| = \|\mathbf{F}_{T_i} \mathbf{u}_{T_i}\| = 1, \quad (25)$$

where \mathbf{u}_Q and \mathbf{u}_{T_i} are called canonical variates and ρ is the canonical cosine similarity. The above is inspired by canonical correlation analysis (CCA) [33].

The canonical cosine similarity ρ and canonical variates $\mathbf{u}_Q, \mathbf{u}_{T_i}$ can be obtained by solving the coupled eigenvalue problems as follows (Derivation is given in the appendix):

$$\begin{aligned} (\mathbf{F}_Q^T \mathbf{F}_Q)^{-1} (\mathbf{F}_Q^T \mathbf{F}_{T_i}) (\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} (\mathbf{F}_{T_i}^T \mathbf{F}_Q) \mathbf{u}_Q &= \rho^2 \mathbf{u}_Q, \\ (\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} (\mathbf{F}_{T_i}^T \mathbf{F}_Q) (\mathbf{F}_Q^T \mathbf{F}_Q)^{-1} (\mathbf{F}_Q^T \mathbf{F}_{T_i}) \mathbf{u}_{T_i} &= \rho^2 \mathbf{u}_{T_i}. \end{aligned} \quad (26)$$

Fig. 13. (a) Examples of correct detections on the UIUC single-scale car test set [53]. (b) Examples of correct detections on the UIUC multi-scale car test set. Confidence level α was set to 0.99 and RM only above the threshold τ corresponding to α is embedded in test images. Bounding boxes are drawn at the correct locations. In case of a multiple detection, a red bounding box indicates higher resemblance to Query than a blue bounding box.

The positive square root of eigenvalues ρ^2 is the ‘‘Canonical Cosine Similarity’’. If $\mathbf{F}_Q, \mathbf{F}_{T_i}$ are each composed of a single vector ($\text{colstack}(\mathbf{F}_Q), \text{colstack}(\mathbf{F}_{T_i})$), the above equations reduce to $\frac{(\text{colstack}(\mathbf{F}_Q)^T \text{colstack}(\mathbf{F}_{T_i}))^2}{\|\text{colstack}(\mathbf{F}_Q)\|^2 \|\text{colstack}(\mathbf{F}_{T_i})\|^2} = \rho^2$ which is just the squared cosine similarity defined earlier in Section II-B.

Now, we take a closer look at the particular case of color images where $q = 3$. A natural question here is whether we can gain more if we use the color information instead of using only the luminance channel as we have so far. The answer to this question is positive. There exist many color spaces such as RGB, YCbCr, CIE L*a*b* etc. We observe that CIE L*a*b* color model provides the most discriminative information among all as also observed by Shechtman and Iran [7]. We define the respective RM⁷ as the summation of mapping function $f(\rho_i(\ell))$ of CCS $\rho_i(\ell)$ between a set of features which are calculated from each channel ($\ell = 1, \dots, q$), where $\sum_{\ell=1}^{d_c} \frac{\rho_i^2(\ell)}{1-\rho_i^2(\ell)}$ (d_c is the number of canonical cosine similarity values $\rho_i(\ell)$ greater than zero). Also illustrated in the next section, the color approach based on CCS not only provides better discriminative power, but also gives more accurate localization results than the luminance channel only does.

V. EXPERIMENTAL RESULTS

In this section, we demonstrate the performance of the proposed method with comprehensive experiments on three datasets; namely, the UIUC car dataset [53], MIT-CMU face dataset [54],

⁷Again as mentioned earlier, note that $\sum_{\ell=1}^{d_c} \frac{\rho_i^2(\ell)}{1-\rho_i^2(\ell)}$ is analogous to the Lawley-Hotelling trace test statistic $\sum \frac{\rho^2}{1-\rho^2}$ which is used in the significance test of canonical variates in canonical correlation analysis [33], [46].

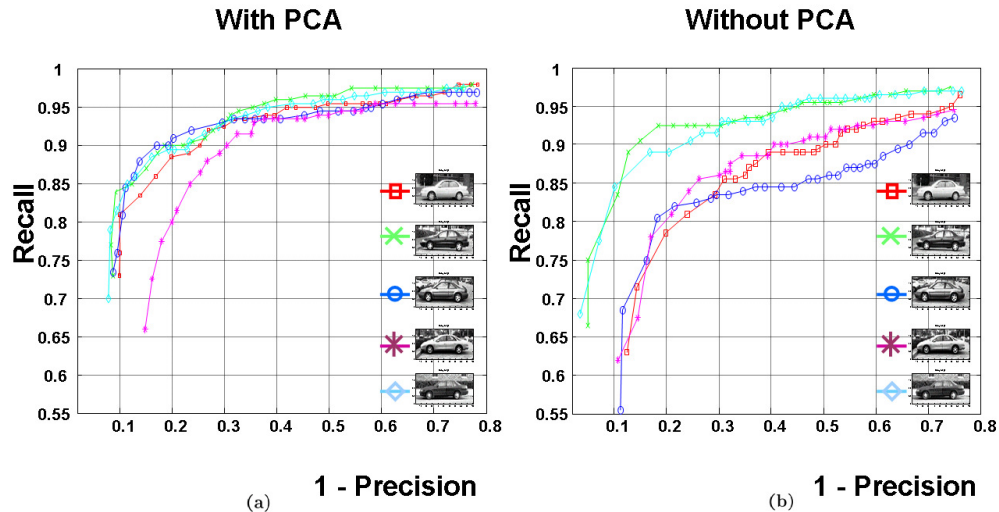

Fig. 14. (a) Recall versus 1-Precision curves of the proposed method (b) Recall versus 1- Precision curves of the proposed method without PCA on the UIUC single-scale car test set [53] using 5 different query images.

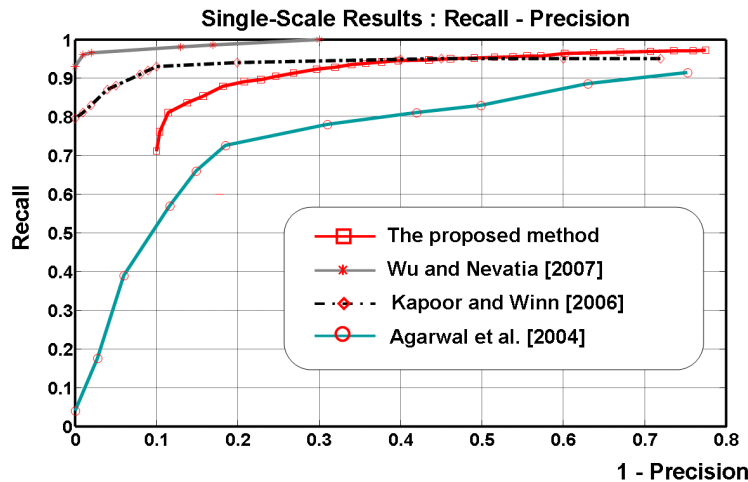

Fig. 15. Comparison of Recall versus 1-Precision curves between the proposed method and state-of-the-art methods [53], [55], [56] on the UIUC single-scale test set [53].

and Shechtman’s general object dataset [7]. The proposed algorithm provides a series of bounding boxes around objects of interest using the criterion described in [53]. More specifically, if the detected region by the proposed method lies within an ellipse of a certain size centered around the ground truth, we evaluate it as a correct detection. Otherwise, it is counted as a false positive. Eventually, we compute *Precision* and *Recall* defined as

$$\text{Recall} = \frac{TP}{nP}, \quad \text{Precision} = \frac{TP}{TP + FP}, \quad (27)$$

where, TP is the number of true positives, FP is the number of false positives, nP is the total number of positives in dataset, and $1 - \text{Precision} = \frac{FP}{TP + FP}$. Experimental results on each

dataset will be presented as recall versus (1-precision) curve and Detection equal-error rate⁸ in the following sections.

A. Car detection

The UIUC car dataset [53] consists of learning and test sets. The learning set contains 550 positive (car) images and 500 negative (non-car) images. The test set is divided into two parts: 170 gray-scale images containing 200 side views of cars with size of 100×40 , and 108 gray-scale images containing 139 cars at various sizes with a ratio between the largest and smallest car of about 2.5. Since our method is training-free, we use only one query image at a time from the 550 positive examples.

1) *Single-scale test set:* We compute LSK of size 9×9 as descriptors, as a consequence, every pixel in Q and T yields an 81-dimensional local descriptor \mathbf{W}_Q and \mathbf{W}_T respectively. The smoothing parameter h for computing LSKs was set to 2.1. We end up with $\mathbf{F}_Q, \mathbf{F}_T$ by reducing dimensionality from 81 to $d = 4$ and then, we obtain RM by computing the MCS measure between $\mathbf{F}_Q, \mathbf{F}_T$. The threshold τ for each test example was determined by the confidence level $\alpha = 0.99$. Fig. 13 (a) shows the output of the proposed method on single-scale test images.

We conducted an experiment by computing RM without performing PCA in order to verify that the use of dimensionality reduction step (PCA) plays an important role in extracting only salient features and improving the performance. We also repeated these experiments by changing the query image and computing precision and recall. In Fig. 14, recall-precision curves represent a performance comparison between the proposed method and the proposed method without PCA using 5 different query images. We can clearly see that the performance of our system is not terribly affected by a choice of the query images, but is quite consistent. Furthermore, PCA consistently contributes to a performance improvement. The detection equal-error rates comparison is provided in Table I as well.

To show an overall performance of the purposed method on five different query images, we summed up TP and FP over the entire experiment, then computed recall and precision at various steps of the threshold value τ according to the confidence level α . Note that, to the best of our knowledge, there are no other training-free methods evaluated on the UIUC dataset

⁸Note that Detection equal-error rate is a detection (recall) rate when a recall rate is the same as the precision rate.

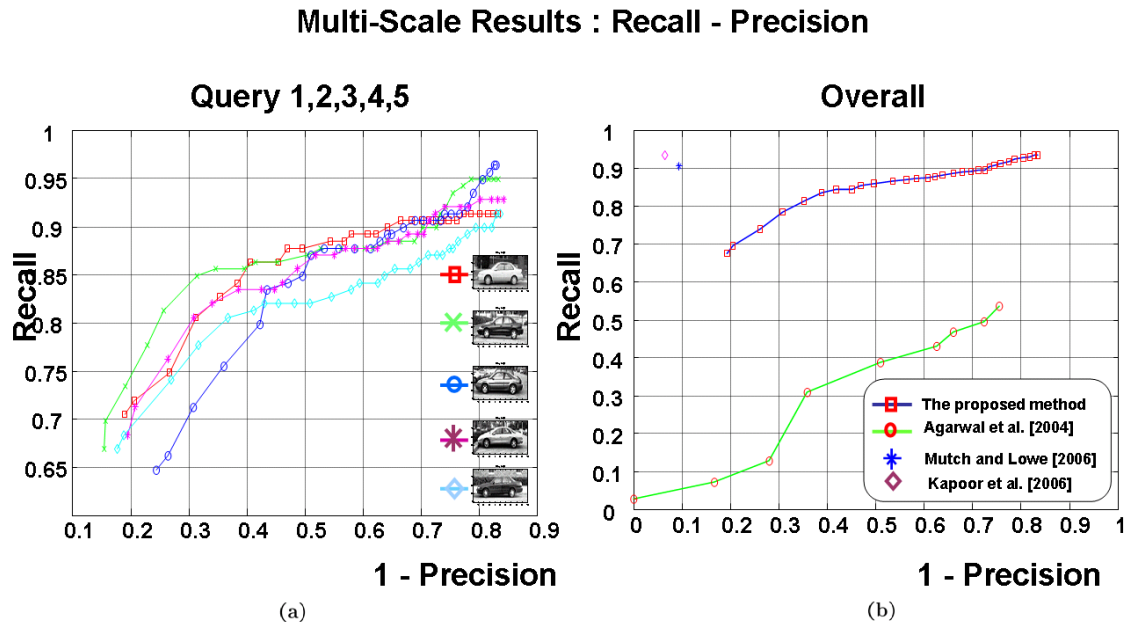

Fig. 16. (a) Recall versus 1-Precisions curve using 5 different query images (b) Comparison of Recall versus 1-Precision curves between the proposed method and state-of-the art methods [56], [57], [53] on the UIUC multi-scale test set [53].

[53], and thus, comparison is largely only made with state-of-the-art training-based methods. The proposed method which is training-free performs favorably against state-of-the-art training-based methods [53], [55], [56] which use extensive training as shown in Fig. 15.

TABLE I

SINGLE-SCALE RESULT: DETECTION EQUAL-ERROR RATES ON THE UIUC SINGLE-SCALE CAR TEST SET [53]

The proposed method w/o PCA	Query 1	Query 2	Query 3	Query 4	Query 5	Agarwal et al. [53] (1)	Wu and Nevatia [55]	Mutch and Lowe [57]
Detection rates	79.29 %	88.12 %	81.11 %	80.41 %	87.11 %	77.08 %	97.5 %	99.94 %
The proposed method	Query 1	Query 2	Query 3	Query 4	Query 5	Agarwal et al. [53] (2)	Kapoor and Winn [56]	Lampert et al. [58]
Detection rates	85.26 %	87.27 %	87.13 %	80.57 %	86.73 %	76.72 %	94.0 %	98.5 %

2) *Multi-scale test set*: As explained in Section IV, we construct a multi-scale pyramid of the target image T : 5 scales with scale factors 0.4, 0.6, 0.8, 1, and 1.2. More specifically, we reduce the target image size by steps of 20% up to 40% of the original size and upscale the target image by 20% so that we can deal with both cases of either the size of objects in the target images being bigger or smaller than the query. The rest of the process is similar to the single-scale case. Fig. 16 (b) shows examples of correct detections using τ corresponding to $\alpha = 0.99$. The overall performance improvement of the proposed method (using 5 different query images) over Agarwal et al. [53] is even greater (over 30%) on the multi-scale test set as

TABLE II

MULTI-SCALE RESULT: DETECTION EQUAL-ERROR RATES ON THE UIUC MULTI-SCALE CAR TEST SET [53]

The proposed method	Query 1	Query 2	Query 3	Query 4	Query 5	Agarwal et al. [53]	Mutch and Lowe [57]	Kapoor and Winn [56]	Lampert et al. [58]
Detection rates	75.47 %	77.66 %	70.21 %	75.00 %	74.22 %	43.77 ~ 44.00 %	90.6 %	93.5 %	98.6 %

shown in Table II and Fig. 16. As for the interpretation of the performance on the UIUC car dataset (both single-scale and multi-scale cases), our methods show performance that is not far from the state-of-the-art training-based methods, except that it requires *no training* at all.

B. Face detection

We showed the performance of the proposed method in the presence of a moderate scale variation (a ratio between the largest and smallest object of about 2.5) in the previous section. In this section, we further evaluate our method on more general scenario where the scale ratio between the largest and smallest is over 10 and large rotations of objects may exist. Therefore, a test set is chosen from a subset of the MIT-CMU face dataset [54]. The test set is composed of 43 gray-scale images⁹ containing 149 frontal faces at various sizes and 20 gray-scale images¹⁰ containing 30 faces with various rotations. A query face image of size 35×36 was employed as shown in Fig. 17, and images for a rotation experiment were resized so that faces are about the same size as the query face. Such parameters as the smoothing parameter (h), LSK size (P), confidence level (α) remain same as the ones used in the UIUC car test sets. However, we increased scale steps for the multi-scale pyramid up to 29, and rotation steps were set to 24 (i.e., rotate the query image by 15 degrees) to achieve an accurate rotation estimation. Fig. 17, Fig. 18, and Fig. 19 show that the proposed method is capable of detecting and localizing faces at distinct scale and rotation angle even in the presence of large variations in scale and rotation. We

⁹The 43 images (from the web:<http://vasc.ri.cmu.edu/idb/html/face/index.html>) are listed as follows: aerosmith-double.gif, blues-double.gif, original2.gif, audrey1.gif, audrey2.gif, baseball.gif, cfb.gif, cnn1714.gif, cnn2020.gif, cnn2600.gif, crimson.gif, ew-courtney-david.gif, gpripe.gif, hendrix2.gif, henry.gif, john.coltrane.gif, kaari1.gif, kaari2.gif, kaari-stef.gif, knex0.gif, lacrosse.gif, married.gif, police.gif, sarah4.gif, sarah_live_2.gif, tammy.gif, tori-crucify.gif, tori-entweekly.gif, tp.gif, voyager2.gif, class57.gif, trek-trio.gif, albert.gif, madaboutyou.gif, frisbee.gif, me.gif, speed.gif, ysato.gif, wxm.gif, torrance.gif, mona-lisa.gif, karen-and-rob.gif, and Germany.gif.

Fig. 17. Detection Results on the MIT-CMU multi-scale test set [54]. α was set to 0.99. Hand-drawn faces on the white board were also detected using a real face query image.

repeated the experiment by changing the query image. Fig. 20 shows Recall versus 1-Precision curves and (for the sake of completeness) corresponding receiver operating characteristic (ROC) curves with respect to two different queries. Note that, in the ROC curve, detection rate P_d and false alarm rate P_f are defined as $\frac{TP}{nP}(= recall)$ and $\frac{FP}{FP+TN}$ respectively, where TN is the number of true negatives. As seen in Fig. 20, the performance of our method on this test set is consistent with the results in the UIUC car test sets. More specifically, the performance of the proposed method is little affected by the choice of similar query images and is quite stable.

C. General object detection

We have shown the performance of the proposed method on data sets composed of gray-scale images which contain specific objects such as car and face. In this section, we have applied our method to a more difficult scenario where general real-world images containing flowers, hearts, and human poses are considered. Furthermore, *rough hand-drawn sketches* are used as a query instead of real images. Shechtman et al.'s general object dataset [7] consists of many challenging pairs of color images (60 pairs with queries such as flowers, hearts, peace symbols, face, and human poses; see Fig. 5). In order to justify the usefulness of the MCS measure for this dataset and to further verify the advantage of the CCS defined in Section IV-C over the MCS measure, we begin with evaluating the proposed method on the luminance channel only. In Fig. 21, some

Fig. 18. Detection Results on the MIT-CMU multi-scale test set [54]. α was set to 0.99. Among 57 faces present, we detected 54 faces at a correct location with 4 false alarms.

Fig. 19. Detection Results on the MIT-CMU multi-rotation test set [54]. α was set to 0.99.

examples of RM are shown. Fig. 22 and Fig. 23 show that the proposed method is able to detect and localize reliably.

We further justify the use of LSKs by comparing the performance with state-of-the-art local descriptors evaluated in [16] as similarity done in [7]. We densely computed such local descriptors as *gradient location-orientation histogram* (GLOH) [16], *Shape Context* [59], and SIFT [13] using the implementation in [16]. By replacing LSKs with these descriptors, but keeping the rest of the steps the same, we repeated the experiment on this test set. The Precision-Recall curve in Fig. 24 verifies that our LSKs have more discriminative power than other local descriptors. The proposed method is also evaluated on full CIE $L^*a^*b^*$ data. If we look at recall rates

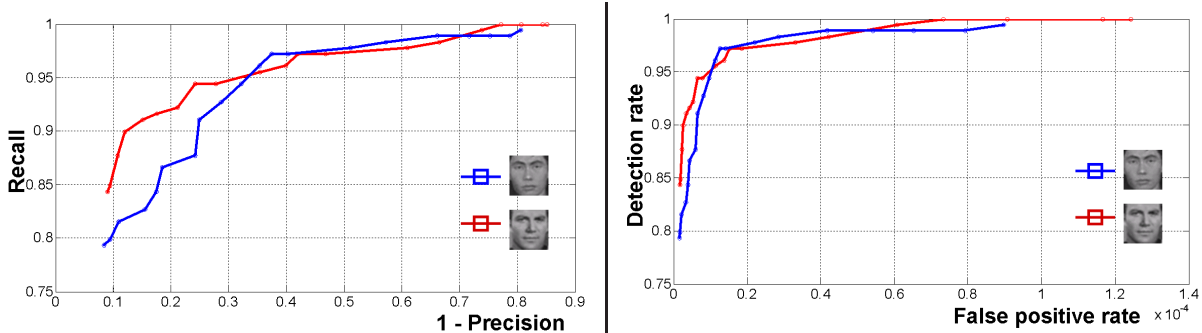

Fig. 20. Left: Precision-Recall curves, Right: ROC curves on the MIT-CMU test set [54] using 2 different query images. Note that detection rate P_d and false alarm rate P_f are defined as $\frac{TP}{n_P}$ ($= recall$) and $\frac{FP}{FP+TN}$ respectively, where TN is the number of true negatives.

Fig. 21. Some examples of detection results with RMs in Shechtman’s object test set [7]. RMs are shown in bottom row.

in the range of $0 \leq (1\text{-precision}) \leq 0.1$ in Fig. 24, we can see that full CIE $L^*a^*b^*$ data provide more information, and thus CCS outperforms the MCS measure as also observed in [7]. Consistent with these results, it is worth noting that Shechtman and Irani [7] also showed that their local self-similarity descriptor clearly outperformed other state-of-the-art descriptors in their ensemble matching framework. However, the performance figures they provide are rather incomplete. Namely, they mentioned 86% detection rate without specifying either any precision rates or false alarm rates. Therefore, we claim that our proposed method is more general and practical than the training-free detection method in [7].

VI. CONCLUSION AND FUTURE DIRECTIONS

In this paper, we have proposed a novel and powerful training-free non-parametric object detection framework by employing local *steering* kernels (LSKs) which well capture underlying data structure, and by using the “Matrix Cosine Similarity” (MCS) measure. We have justified the approach using a naive Bayes decision which leads to the use of MCS measure. The

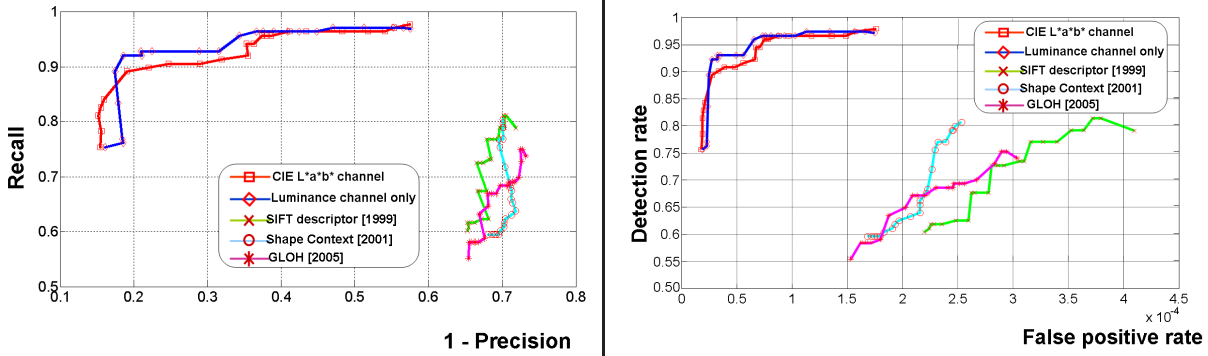

Fig. 24. Left: Comparison of Recall versus 1-Precision curves between luminance channel only and CIE L*a*b* channel on the Shechtman’s test set [7]. It is clearly shown that such descriptors as SIFT [13], GLOH [16], Shape Context [59] turn out to be inferior to LSKs in terms of discriminative power. Right: Comparison of ROC curves. Note that detection rate P_d and false alarm rate P_f are defined as $\frac{TP}{nP}$ ($= recall$) and $\frac{FP}{FP+TN}$ respectively, where TN is the number of true negatives.

when vector-valued images are available though this requires further study. Challenging sets of real-world object experiments have demonstrated that the proposed approach achieves a high detection accuracy of objects of interest even in completely different context and under different imaging conditions. Unlike other state-of-the-art learning-based detection methods, the proposed framework operates using a *single* example of an image of interest to find similar matches; does not require any prior knowledge (learning) about objects being sought; and does not require any segmentation or pre-processing step of the target image. The proposed framework is general enough as to be extendable to 3-D for such applications as action recognition, suspicious behavior detection etc. using analogous 3-D LSKs [35], [60]. Since the proposed system is designed with detection accuracy as a high priority, improvement of the computational complexity of the proposed method via an efficient searching method such as a branch and bound search [58] is also a direction of future research worth exploring. Additionally, for the proposed method to be feasible for scalable image retrieval, we may adopt the idea of encoding the features as proposed in [61], [62]. Interestingly, the detection framework proposed in our paper can also be useful for solving the bottom-up saliency detection problem [32] by computing a self-resemblance map between a center feature set (as a query) and surrounding feature sets (as a target). We also expect to be able to apply the proposed method to other challenging medical/ diagnostic problems such as change detection in medical imaging applications.

APPENDIX

The Lagrangian objective function to the minimization problem in Equation (25) is

$$f(\lambda_Q, \lambda_T, \mathbf{u}_Q, \mathbf{u}_{T_i}) = \mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_{T_i} \mathbf{u}_{T_i} - \frac{\lambda_Q}{2} (\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_Q \mathbf{u}_Q - 1) - \frac{\lambda_{T_i}}{2} (\mathbf{u}_{T_i}^T \mathbf{F}_{T_i}^T \mathbf{F}_{T_i} \mathbf{u}_{T_i} - 1) \quad (28)$$

Taking derivatives with respect to \mathbf{u}_Q and \mathbf{u}_{T_i} , we obtain

$$\frac{\partial f}{\partial \mathbf{u}_Q} = \mathbf{F}_Q^T \mathbf{F}_{T_i} \mathbf{u}_{T_i} - \lambda_Q (\mathbf{F}_Q^T \mathbf{F}_Q \mathbf{u}_Q) = 0 \quad (29)$$

$$\frac{\partial f}{\partial \mathbf{u}_{T_i}} = \mathbf{F}_{T_i}^T \mathbf{F}_Q \mathbf{u}_Q - \lambda_{T_i} (\mathbf{F}_{T_i}^T \mathbf{F}_{T_i} \mathbf{u}_{T_i}) = 0 \quad (30)$$

We pre-multiply $\mathbf{u}_{T_i}^T$ to Equation (30) and also pre-multiply \mathbf{u}_Q^T to Equation (29). By subtracting these two equations, we have

$$\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_{T_i} \mathbf{u}_{T_i} - \lambda_Q (\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_Q \mathbf{u}_Q) - \mathbf{u}_{T_i}^T \mathbf{F}_{T_i}^T \mathbf{F}_Q \mathbf{u}_Q - \lambda_{T_i} (\mathbf{u}_{T_i}^T \mathbf{F}_{T_i}^T \mathbf{F}_{T_i} \mathbf{u}_{T_i}) = 0, \quad (31)$$

where $(\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_{T_i} \mathbf{u}_{T_i})^T = \mathbf{u}_{T_i}^T \mathbf{F}_{T_i}^T \mathbf{F}_Q \mathbf{u}_Q$ is a scalar.

Enforcing the constraints $(\mathbf{u}_Q^T \mathbf{F}_Q^T \mathbf{F}_Q \mathbf{u}_Q)^T = (\mathbf{u}_{T_i}^T \mathbf{F}_{T_i}^T \mathbf{F}_{T_i} \mathbf{u}_{T_i})^T = 1$, we are led to the conclusion that $\lambda_Q = \lambda_{T_i}$. We define $\rho = \lambda_Q = \lambda_{T_i}$. Assuming $\mathbf{F}_{T_i}^T \mathbf{F}_{T_i}$ is invertible from Equation (30),

$$\mathbf{u}_{T_i} = \frac{(\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} \mathbf{F}_{T_i} \mathbf{F}_Q \mathbf{u}_Q}{\rho} \quad (32)$$

and so plugging in Equation (29), we have

$$\frac{(\mathbf{F}_Q^T \mathbf{F}_{T_i})(\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} (\mathbf{F}_{T_i} \mathbf{F}_Q) \mathbf{u}_Q}{\rho} = \rho (\mathbf{F}_Q^T \mathbf{F}_Q) \mathbf{u}_Q \quad (33)$$

Assuming $\mathbf{F}_Q^T \mathbf{F}_Q$ is also invertible, we are left with

$$(\mathbf{F}_Q^T \mathbf{F}_Q)^{-1} (\mathbf{F}_Q^T \mathbf{F}_{T_i})(\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} (\mathbf{F}_{T_i} \mathbf{F}_Q) \mathbf{u}_Q = \rho^2 \mathbf{u}_Q. \quad (34)$$

Similarly, we have

$$(\mathbf{F}_{T_i}^T \mathbf{F}_{T_i})^{-1} (\mathbf{F}_{T_i}^T \mathbf{F}_Q)(\mathbf{F}_Q^T \mathbf{F}_Q)^{-1} (\mathbf{F}_Q^T \mathbf{F}_{T_i}) \mathbf{u}_{T_i} = \rho^2 \mathbf{u}_{T_i}. \quad (35)$$
